CONTENTS

OF

THE SECOND VOLUME.

PART IV.—DISEASES OF THE VARIOUS ORGANS :

VIZ. OF THE ORGANS OF SPECIAL SENSE, OF INNERVATION AND LOCOMOTION,
OF RESPIRATION AND DIGESTION, AND OF THE SKIN.

DISEASES AND INJURIES OF THE EYE.

By J. DIXON,

Consulting Surgeon to the Royal London Ophthalmic Hospital, Moorfields.

Edited by J. W. HULKE, F.R.S.

Surgeon to the Mid'ler Hospital, and to the Royal London Ophthalmic Hospital.

CHAPTER I.

OPTICAL DEFECTS.

	PAGE		PAGE
Refraction	1	Ecchymosis of the subconjunctival tissue	26
Accommodation	3	Pinguecula	26
Myopia, Hypermetropia, Presbyopia, and Astigmatism, their clinical deter- mination and correction	5	Pterygium	27
		Fatty tumours	27
		Cysticercus telæ cellulosee	28
		Stains from nitrate of silver	28

CHAPTER II.

EXAMINATION OF THE EYE.

Examination of the conjunctiva and cornea	7
Ophthalmoscopic examination	8
Ophthalmoscopic appearances of the healthy eye	10

CHAPTER III.

DISEASES OF THE CONJUNCTIVA AND ITS AREOLAR TISSUE.

Inflammation of the conjunctiva (<i>oph- thalmia</i>)	12
Catarrhal ophthalmia	14
Phlyctenular or pustular ophthalmia	15
Purulent ophthalmia	16
Gonorrhoeal ophthalmia	18
Granular conjunctiva	20
Purulent ophthalmia of infants (<i>oph- thalmia neonatorum</i>)	22
Chronic ophthalmia	24
Injuries of the conjunctiva	25
Edema of the subconjunctival tissue :	26

CHAPTER IV.

DISEASES AND INJURIES OF THE CORNEA.

Conical cornea	29
Arcus senilis	31
Inflammation of the cornea (<i>keratitis</i>)	31
Scrofulous or strumous 'ophthalmia'	33
Interstitial keratitis	35
Keratitis with suppuration	37
Exanthematous 'ophthalmia'	39
Ulcers of the cornea	40
Opacities of the cornea	41
Injuries of the cornea :	
Abrasion	42
Contusion	43
Incised and punctured wounds	43
Foreign bodies	45
Entozoa in the anterior chamber	46

CHAPTER V.

DISEASES OF THE SCLEROTIC.

Inflammation of the sclerotic	47
Injuries of the sclerotic ; wounds	48
Rupture of the sclerotic, with displace- ment of the lens	49

CHAPTER VI.

DISEASES AND INJURIES OF THE IRIS.

	PAGE
Congenital defects	50
Persistent membrana pupillaris	51
Mydriasis	51
Myosis	52
Iritis	52
Traumatic iritis	53
Rheumatic iritis	55
Syphilitic	56
In infants	59
Scrofulous	60
Gonorrhoeal and arthritic iritis	61
Use of atropine	62
Sequels of iritis	63
Operations on the iris for artificial pupil	64
After-treatment of artificial pupil	68

CHAPTER VII.

DISEASES OF THE CHOROID, RETINA
AND OPTIC NERVE.

Coloboma	69
Hyperemia of the choroid	70
Choroiditis	70
Congestive swelling of optic papilla	71
Neuritis, Neuro-retinitis	71
Atrophy of the optic nerve	72
Retinitis	73
Syphilitic retinitis	73
Chlorotic retinitis	74
Retinitis pigmentosa	74
Retinal hæmorrhage	74
Embolism of central artery of retina	75
Detached retina	75
Tumours of the choroid and retina	76

CHAPTER VIII.

VISUAL DISORDERS.

Hemiopsia, Hemipia	77
Hemeralopia	78
Nyctalopia	78
Colour-blindness	78

CHAPTER IX.

DISEASES OF THE VITREOUS BODY.

Hæmorrhage into the vitreous body	79
Inflammation	79
Sparkling synchysis	79
Entozoa	79
Muscæ volitantes	81
Opacities in the vitreous humour	81

CHAPTER X.

DISEASES OF THE LENS AND ITS CAPSULE.

Abnormal position of the lens	82
Cataract	82
Congenital cataract	83
Cataract in adults	85
Traumatic cataract	86
Operations for cataract	87
Solution	87
Extraction	90

After-treatment	93
Linear extraction	99
Scoop extraction	100
Peripheral linear extraction	101
Operations for opaque capsule	102

CHAPTER XI.

GLAUCOMA.

Symptoms	105
Treatment by iridectomy	108
" sclerotomy	109

CHAPTER XII.

DISEASES OF THE LACRYMAL APPARATUS.

Examination of the lacrymal efferent passages	110
Inflammation of the lacrymal sac	111
Lacrymal obstructions, treatment	111
Dacryolithes	114
Dacryops	114

CHAPTER XIII.

DISEASES AND INJURIES OF THE EYELIDS.

Spasm of orbicularis palpebrarum	115
Epicanthus	115
Ptosis	115
Entropion	115
Ectropion	116
Trichiasis	117
Stye	117
Abscess of meibomian glands	117
Ophthalmia tarsi	118
Phtheiriasis	118
Cysts	119
Warts	119
Nævi	119
Fibrous (dermoid) cysts	119
Molluscum	120
Carcinoma	120
Ecchymosis	121
Emphysema	121
Wounds	121

CHAPTER XIV.

DISEASES OF STRUCTURES WITHIN
THE ORBIT.

Protrusion of the eyeball	121
Dislocation of the eyeball	122
Hydatids, Carcinoma, Exostoses	122
Abscess	122
Affections of the orbital nerves:	
Anatomy	123
Palsy of third cranial nerve	123
" sixth cranial nerve	123
" fourth cranial nerve	123
Treatment of ocular palsies	124
Strabismus	124
Operations for squint	125
Enucleation of eyeball	126
Use of chloroform in ophthalmic surgery	127

DISEASES AND INJURIES OF THE EAR.

Rewritten by W. B. DALBY, Esq.
Aural Surgeon to St. George's Hospital.

	PAGE		PAGE
Examination of the ear.	120	Catheterism of the Eustachian tube . . .	142
Specula	120	Affections of the tympanum . . .	143
Mirror	130	Relaxation and collapse of the mem- brane	145
Politzer's method of inflating the tym- pana	131	Accumulations of serous fluid and mucus	145
<i>The External Ear.</i>		Incision of the tympanic membrane . . .	147
Malformations	131	Inflammation of the tympanum . . .	148
Tumours of the auricle	132	Perforation of the membrana tympani . .	149
Foreign bodies in the external auditory canal	132	Artificial membranes	150
Exostoses in the external auditory canal .	134	Facial paralysis	150
Cerumen in the external auditory canal .	135	Polypus of the ear	151
Fungi	136	Abscess in the mastoid process . . .	152
Collapse of the cartilage	136	Fatal results of inflammation of the middle ear	153
Eczema	136	Malignant disease of the ear	154
Boils	137	Necrosis and caries of the temporal bone	155
Abscess	137	<i>Syphilitic Affections of the Ear.</i>	
Polypi	137	Inherited syphilis	155
<i>The Middle Ear.</i>		Constitutional syphilis	155
Anatomy	138	<i>Internal Ear.</i>	
Membrana tympani	138	Disease of the nervous portions . . .	156
Injuries of the membrana tympani . . .	139	Nervous diseases	157
Non purulent catarrh of the middle ear	140	Menière's disease	157
Obstruction of the Eustachian tube . . .	141	Deafness associated with parturition .	158

AFFECTIONS OF THE MUSCULAR SYSTEM.

By the late J. LOCKHART CLARKE, Esq., M.D., F.R.S.

Edited by ARTHUR E. BARKER, Esq.
Assistant Surgeon to University College Hospital.

Rupture of muscles	150	Neoplasms	160
Inflammation of muscle	161	Entozoa	170
Syphilitic inflammation	162	<i>Affections of Tendons, their Sheaths and Bursa.</i>	
Muscular atrophy	163	Injuries of tendon	171
1. Simple atrophy	163	Inflammation of tendons	172
2. Progressive muscular atrophy . . .	163	Tumours of tendons	172
3. Granular degeneration	164	<i>Synovial Sheaths.</i>	
4. Fatty degeneration	164	Simple acute teno-synovitis	173
5. Waxy or vitreous	164	Ganglion	173
Pathology	165	Compound ganglion	174
Etiology	165	Paronychia tendinosa	175
Treatment	166	Treatment	175
Consecutive paralyses	167	<i>Bursæ.</i>	
Degeneration with apparent hyper- trophy	167	Bursitis, chronic and acute	177
Symptoms and course	167		
Morbid anatomy	167		
Treatment	167		
Ossification of muscle	168		
Tumours	169		

DISEASES AND INJURIES OF NERVES.

PART I.

NERVE LESIONS AND OTHER MORE IMMEDIATE EFFECTS.

By the late J. LOCKHART CLARKE, M.D.

Edited by C. E. BROWN-SÉQUARD, M.D. F.R.S.

*Professor of Medicine at the College of France.**Diseases of Nerves.*

	PAGE
Inflammation of nerves (Neuritis)	178
Pathological anatomy of neuritis	178
Acute neuritis	179
Chronic neuritis	179
Idiopathic neuritis	179
Traumatic neuritis	180
Diagnosis	180
Treatment	180
Ulceration of nerves	180

Tumours of Nerves.

False neuromata	181
Painful subcutaneous tubercle	182
Symptoms of neuromata	182
Treatment of neuromata and painful subcutaneous tubercle	182
Tubercle	183
Cancer	183
Cysts	183
Hypertrophy	183
Atrophy	183

Injuries of Nerves.

Contusion	184
Compression	184

	PAGE
Laceration	185
Ligature	186
Complete division	186
Incomplete division	187
Puncture	187
Incised wounds	188
Symptoms (tabular classification)	190
Treatment of injuries	190

Nutritive and other Changes resulting from Injuries and Diseases of Nerves.

1. Changes due to injuries of nerves:	
a. Alteration of temperature	192
b. Nutritive changes in the skin and its appendages	193
c. Alteration of secretions	195
d. Various alterations of joints and bones	195
e. Atrophy and contraction of muscles	195
Treatment	196
2. Changes due to idiopathic affections of nerves:	
Nutritive changes in the skin	197
Disorders of sensibility and motion after asphyxia by carbonic acid	197

PART II.

REMOTER CONSEQUENCES OF NERVE-LESIONS.

By C. E. BROWN-SÉQUARD, M.D. F.R.S.

Professor of Medicine at the College of France.

Introduction	198
--------------	-----

Section I. *Affections of the Nerve-Centres and other Organs caused by an Injury to, or a Disease of, a Nerve.*

Epilepsy	200
Tetanus	201
Hysteria	202
Catalepsy	203
Chorea	203
Hydrophobia	203
Tremulous movements	203
Rotatory convulsions	204
Local convulsions	204
Contracture of blood-vessels	204
Paralysis	204
" of lower limbs	205
Anæsthesia	206
Amaurosis	206
Deafness	207
Loss of smell, taste, and hearing	207

Collapse	207
Neuralgia	207
Delirium	208
Aphasia	208
Inflammation	208
Concussion	209
Apoplexy	209
Muscular atrophy	209
Atrophy of the cellular tissue	210
Hypertrophy	210
Various kinds of alterations of nutrition and secretion	210

Section II. *General Features and Rules of Treatment of the various Affections caused by an Irritation of a Nerve.*

Symptomatology	211
Local treatment	212
General treatment	213

PART III.

SUTURE AND STRETCHING OF NERVES.

By C. E. BROWN-SÉQUARD, M.D. F.R.S.

Professor of Medicine at the College of France.

Suture of nerves	214	e. Nerve-stretching against paralysis, anæsthesia, and lepra anæsthetica	220
Stretching of nerves	215	f. Nerve-stretching in locomotor ataxy	220
1. Weight that can be borne by nerves without being torn	215		
2. Extent of stretching that takes place in nerves before they break	216		
3. Changes in structure under stretching	216	<i>General Features in Nerve-Stretching, and its Curative Importance.</i>	
4. Alteration in physiological properties and loss of function in stretched nerves	216	Nerve-stretching acts on the nervous centres and through them on distant nerves	221
5. Mode of influence of stretching of a nerve on the nervous centres	216	A considerable stretching produces structural alterations of the nerve, and is therefore equivalent to neurotomy	221
a. Nerve-stretching against neuralgia	217	Regeneration more rapid after stretching than after neurotomy	221
b. Nerve-stretching in cases of spasmodic tic and local tonic spasm	218	Importance of nerve-stretching in various affections	221
c. Nerve-stretching in tetanus	219		
d. " " against an epileptiform affection	220		

LOCOMOTOR ATAXY.

By the late J. LOCKHART CLARKE, M.D.

Edited by C. E. BROWN-SÉQUARD, M.D. F.R.S.

Professor of Medicine at the College of France.

Motory symptoms	223	Pathological anatomy	225
Anæsthesia	224	Prognosis and treatment	225
Analgesia	224		

ORTHOPÆDIC SURGERY.

By W. J. LITTLE, M.D.

Formerly Physician to the Royal Orthopædic Hospital.

Pathology of deformities	227	Gymnastic apparatus	241
Contraction from disease, injury, &c.	227	Talipes equinus	243
" " disease of the nerve-centres	228	" valgus, equino-valgus, and calcaneo-valgus	245
Contraction from congenital defects	228	Irregular congenital foot distortions	247
Secondary changes	228	Distortions arising at the moment of birth	247
General description of the operation of tenotomy	229	Spastic contractions arising in infancy from cerebro-spinal disease	249
Description of individual deformities—		Flat-foot or spurious valgus	250
Congenital club-foot (talipes varus congenitus)	229	Section of peroneal tendons	252
Primary and secondary changes in club-foot	230	Contraction of the upper extremity from spasm and paralysis	252
Ætiology of club-foot	231	Contraction of palmar fascia	252
Grades of club-foot	232	Wry-neck (congenital)	255
Treatment in its various degrees	235	Division of the sterno-mastoid	257
Section of posterior tibial tendon	236	Spasmodic wry-neck	258
" anterior tibial tendon	238	Paralytic wry-neck	259
" tendo Achillis	238	Wry-neck from disease of the spine	260
Instruments required after operation	238	Knock-knee	261
Relapsed club-foot	238	Orthopædic operations for curvature of bones	265

	PAGE		PAGE
Anchylolosis of knee and other joints . . .	265	Division of flexor tendons of fin-	...
Treatment by gradual mechanical		gers and toes	271
extension	267	Forcible extension	272
Treatment by division of ham-		" " under chloro-	
string tendons	270	form	273
Treatment by subcutaneous separa-		Section of the neck of the femur .	274
tion of tibia and femur	270	Emotional and hysterical contraction	274
Division of muscles near hip	271		

DISEASES OF THE BONES.

By T. HOLMES, ESQ.

Surgeon to St. George's Hospital.

<i>Simple Inflammation and its Consequences.</i>		Rheumatism in bone	311
General sketch of the inflammatory		Mollities ossium	312
process in bone	276	<i>Malignant Tumours.</i>	
Ostitis or simple inflammation	278	Cancer or sarcoma in bone	315
Periostitis	280	Kind of cancer and sarcomata found in	
Ostitis deformans	281	bones	315
Diffuse periostitis or acute periosteal		Myeloid tumour	316
abscess	282	Osteoid or calcifying malignant tu-	
Epiphysitis	285	mours	316
Osteo-myelitis or diffused suppura-		Melanotic cancer	317
tion in the interior of bone	285	Symptoms and diagnosis	318
Chronic abscess of bone	287	Treatment	319
Caries or ulceration of bone	289	Pulsatile malignant tumour	320
Necrosis or gangrene of bone—gene-		Osteo-aneurism	320
ral description	293	Treatment of pulsatile tumour	320
Varieties according to extent and		Cancerous ulceration in bone	320
seat	297	<i>Non-Malignant Tumours of Bone.</i>	
Treatment by operation	298	Enchondroma	321
Absorption of necrosed portions	299	Exostosis	324
Reproduction of bone after ne-		Diffused bony (or innocent osteoid)	
crosis	300	tumour	327
Exfoliation of diseased portions of		Cystic tumours	328
bone	301	Fibrous and fibro-cystic tumours	328
Acute necrosis	302	Entozoa in bone	329
<i>Constitutional Affections.</i>		<i>Simple Hypertrophy and Atrophy of Bone.</i>	
Scrofula in bone	303	Hypertrophy	330
Syphilis in bone	306	Atrophy	331
Comparison between syphilitic affec-		Spontaneous fracture	332
tions of bone and skin	308	<i>Wounds of Bone</i>	332
Operative treatment of syphilis in			
bone	310		

DISEASES OF JOINTS.

By ARTHUR A. W. JOHNSTONE, ESQ.

Rewritten by A. E. BARKER, ESQ.

Assistant Surgeon to University College Hospital.

GENERAL PATHOLOGY.

Affections of the Synovial Membrane.

Simple synovitis, acute	334
" " sub-acute	336
" " chronic	336
" "	337
Synovitis from constitutional causes	337
Acute pyæmic synovitis	338
Sub-acute septic synovitis	340
Synovitis in gonorrhœa	340
Syphilitic synovitis	340
Strumous synovitis	342

Gouty inflammation	343
Arthritis deformans	344

Affections of the Ligaments.

Inflammation	348
Hyperæmia	348

Affections of the Cartilages.

Primary changes	348
Secondary changes	349
Ulceration	349

Affections of the Bones.

General pathology	351
Epiphysitis	353
" sub-acute	354
" chronic	354

Loose Cartilages.

Etiology	355
Loose cartilages of inflammatory origin	355
" " traumatic origin	355
" " extraneous origin	356
Symptoms	356
Treatment	356

Anchylosis.

Pathology	358
Fibrous	359
Bony	359

Nervous or Hysterical Affections

Neuromimesis	360
Principles of diagnosis	361

Affections of the Hip.

Simple acute synovitis	363
Acute suppurative synovitis	363
Simple sub-acute and chronic synovitis	366
Pyæmic or septic synovitis	366
Syphilitic disease	367
Strumous disease	367
Differential diagnosis of femoral and synovial coxitis	368
Symptoms of coxitis	369
Treatment of strumous coxitis	372
Coxitis with extensive implication of the acetabulum	376
Gouty coxitis	376
Arthritis deformans	376
Treatment	377
Loose bodies	378
Mimic disease	378

Affections of the Knee.

Simple synovitis, acute	378
" " sub-acute or chronic	379
Treatment	379
Septic synovitis, acute, sub-acute, and chronic	380
Strumous disease	380
Syphilitic affections	385
Gout	385
Arthritis deformans	385
Loose bodies	387
Luxation of the semilunar cartilages	388

Affections of the Ankle.

Simple synovitis	389
Strumous disease	389

Affections of the Tarsal and Metatarsal Joints.

General principles of operations for dis- ease	300
Bunion	391

Affections of the Shoulder.

Synovitis	392
Strumous disease	392
Inflammation of the sub-deltoid bursa	392
Arthritis deformans	394
Septic synovitis	394

Affections of the Elbow.

Synovitis, simple acute	394
" " sub-acute	394
" " chronic	394
Strumous disease	394
Pyæmic affections	395
Arthritis deformans	395

Affections of the Wrist.

Acute synovitis	395
Strumous disease	396
Arthritis deformans	396

Affections of the Temporo-Maxillary Joint.

Arthritis deformans	396
Synovial affections	396
Disease produced by suppuration in the middle ear	397

Affections of Symphysis Pubis.

General considerations	397
Pyæmic affection	397
Strumous disease	397
Primary caries	397
Treatment	397

Sacro-Iliac Disease.

Statistics	397
Symptoms	398
Treatment	399

Affections of the Sacro-Coccygeal Joint.

Inflammation	399
Treatment	399
Coccydynia	400

DISEASES OF THE SPINE.

PART I.

CARIES OF SPINE.

By A. SHAW,

Consulting Surgeon to the Middlesex Hospital.

Edited by A. E. BARKER, Esq.

Assistant Surgeon to University College Hospital.

	PAGE		PAGE
General pathology	401	<i>Lumbar Region.</i>	
Etiology	405	Diagnosis of lumbar caries	416
Secondary changes	406	Treatment	417
Angular curvature	407		
Abscess	408	<i>Abscesses in connection with Caries of</i>	
Nerve symptoms	409	<i>the Vertebrae.</i>	
Principles of treatment	410	General principles of treatment	417
		When they should be opened	418
<i>Cervical Region.</i>		Application of the Listerian method	418
Cervical caries	411	Prognosis	420
Symptoms	411		
Diagnosis	412	<i>Some Unusual Forms of Spinal Caries.</i>	
Treatment	412	Atlo-Axial Disease	420
		Its rarity	420
<i>Dorsal Region.</i>		Ætiology	421
Diagnosis of dorsal caries	413	Syphilitic deposits	421
Abscess	414	Symptoms	422
Pressure on aorta	415	Treatment	423
Constitutional and local treatment	415	Prognosis	424
		Mimic disease of the spine	425

PART II.

SCOLIOSIS, OR LATERAL CURVATURE.

By W. J. LITTLE, M.D.

Formerly Physician to the Orthopedic Hospital.

Anatomy and pathology	426	<i>On Curvature of the Chest and Spine</i>	
Mechanism of production of lateral		<i>after Pleurisy</i>	
curvature	428	True or simple lateral curvature	441
Formation of the curvature	430	Posterior curvature	442
Causes of the rotation	432	Lordosis, or anterior curvature	443
Special appearances at different curves	434		
Changes in form of chest	436	<i>Lordosis from Paralysis, from Hip-</i>	
" " belly	436	<i>Contraction, Luxation, Congenital and</i>	
Shoulders	437	<i>Acquired, and from Excessive Use.</i>	
Diagnosis	439	Congenital hip-luxation	443
Prognosis	439	Paralytic spinal curvature	444
Treatment	439	Acute spasmodic and hysterical sco-	
		<i>liosis</i>	444

SURGICAL DISEASES CONNECTED WITH THE TEETH.

By S. JAMES A. SALTER, F.R.S.

Consulting Dental Surgeon to Guy's Hospital.

<i>Subjects comprised in this essay :</i>	446		
I. Alveolar abscess	447	Pointing of alveolar abscess remote	
Gumboil	447	<i>from origin of abscess</i>	448
Pointing of alveolar abscess inside the		Pointing of alveolar abscess on the face	449
mouth	448	Diagnosis of alveolar abscess	450
		Treatment	450

II. Painful and difficult eruption of wisdom teeth	451	Exostosis	461
In the upper jaw	451	Hypertrophied, dilated fangs	462
In the lower jaw	451	Dentine excrescence	462
Spasmodic contraction of masseter	452	Warty teeth	463
Suppuration and fistula from difficult eruption	452	VI. Abscess of the antrum	464
Treatment	453	Causes and symptoms of antral abscess	465
" of the spasmodic closure of the mouth	454	Treatment	466
III. Tumours of the gum :		VII. Dentigerous cysts	468
Epulis	454	Pathology and mode of development	469
Treatment	456	Summary of recorded cases of such cysts	470
Congenital hypertrophy of the gum and alveoli	456	Symptoms	472
Treatment	458	Treatment	472
Polypus of the gum	458	VIII. Alveolar or maxillary necrosis	473
Treatment	458	Phosphorus disease	473
Vascular tumours	458	Causes	474
Treatment	459	Symptoms	476
Warty tumours of the gum	459	Treatment	478
IV. Tumours of the tooth pulp :		Evanthematous jaw-necrosis	480
Polypus of the pulp	460	Treatment	481
Treatment	460	IX. Hæmorrhage after extraction of teeth	482
Sensitive growth of pulp after fracture	460	Treatment	483
V. Odontomes, or tumours of the hard tissues of the teeth :		X The application of obturators and false-palates in cleft-palate, &c.	484
Enamel nodules	461	Obturators	485
		False-palates	487

DISEASES OF THE MOUTH, PHARYNX, AND ŒSOPHAGUS.

By GEORGE POLLOCK, ESQ.

Consulting Surgeon to St. George's Hospital.

Of the Mouth.

Quinsy ; acute inflammation of the tonsils	480
Symptoms	480
Causes	490
Treatment	490
Diagnosis from other inflammatory affections in this region	492
Chronic inflammation and enlargement of the tonsils	492
Causes of enlarged tonsils	493
Forms	493
Effects	493
Pathological anatomy	494
Treatment	494
Excision of the tonsils	495
Malignant sore-throat (tonsillitis maligna)	495
Ulcerated sore-throat	496
Relaxed uvula	497
Removal of the uvula	497
Tumours of the palate	497
Cleft-palate (congenital)	498
Its mode of origin	499
Development of the mouth	499
Classification and description of different degrees	499
Varying width of cleft	502
Effects of cleft-palate	503
Treatment	503

Age for operation	503
Operations in cases of bifid uvula	504

DISEASES OF THE INTESTINES.

By GEORGE POLLOCK, Esq.

Consulting Surgeon to St. George's Hospital.

Abdominal abscess	706	Stricture from cancer of the bowel or tumours in the neighbourhood	728
Fæcal abscess	707	Relative frequency of these different forms	728
Treatment	708	Diagnosis of the seat of obstruction and of its nature	729
Obstruction of the intestines	709	Treatment of obstruction	730
Causes of obstruction	710	Cases in which colotomy is justifiable	731
Commonly acute:		Opening the peritoneal sac (Littre's operation)	731
Congenital malformation	711	Lumbar colotomy (Amussat's and Calissen's operations)	732
Lodgment of foreign bodies	712	Colotomy	733
Twisting or 'dislocation' of bowel	712	Colectomy for removal of cancerous strictures	735
Strangulation by loops, false membranes, diverticula, &c.	715		
Strangulation by peritoneal pouches, the foramen of Winslow, &c.	715	<i>On the Removal of the Pylorus for Cancer.</i>	
Intussusception	719	Seat and course of cancer of the pylorus	740
Spontaneous cure of intussusception	722	Conditions justifying excision	740
Treatment	723	Billroth's directions for operating	741
Commonly chronic:		After-treatment	742
Habitual constipation—accumulation of fæces	725	History of published cases	743
Injury	726	Paracentesis of the abdomen	745
Chronic peritonitis (tubercular) and abscess	726		
Stricture from chronic disease of the intestine	728		

HERNIA.

By J. BIRKETT, Esq.

Consulting Surgeon to Guy's Hospital.

PART I.

PATHOLOGY AND TREATMENT OF HERNIA IN GENERAL.

General considerations:		Condition of the vaginal process at birth	754
Proportions of the two sexes	747	Of the gradual development of the hernial sac	755
Frequency of hernia at different ages	747	The period of formation	756
Proportion of population affected with hernia	748	" organisation	756
Influence of occupation	749	" contraction	757
Influence of hereditary conformation and other circumstances	749	The two kinds of hernial sac, congenital and acquired	757
Immediate cause of hernia	750	The treatment of reducible hernia—palliative measures	758
Symptoms of hernia in general	751	Trusses	758
Prognosis	751	Radical cure of hernia	760
Nomenclature of hernia	752	Morbid conditions of the hernia	762
The essential parts of the tumour	752	Permanent irreducibility	762
The exciting causes of hernia	752	Obstruction or distension	762
Congenital patency of the vaginal process of the peritoneum	752	Inflammation	762
Description of the changes which take place in this process	753	Strangulation	764

Prolapsus of the rectum	842	Treatment	859
Various conditions :		Dilatation	860
Complicated with piles	843	Incision	860
Treatment	844	Cancer of the rectum	860
Fistula in ano	847	Polypus of the rectum	864
Formation of fistula	847	Warty polypus	865
Various forms of fistula :		Villous tumour	866
Complete and incomplete	848	Pruritus ani	866
Horseshoe fistula	849	Neuralgia of the rectum	867

GENERAL DISEASES OF THE SKIN.

By SIR W. JENNER, BART., F.R.S.

Physician-in-Ordinary to the Queen and the Prince of Wales

The late DR. HILLIER, and the late G. NAYLER, ESQ.

Revised by J. S. BRISTOWE, M.D., F.R.S.

Physician to St. Thomas's Hospital.

Classification of the constitutional affec- tions of the skin	808	Herpes	880
Order 1. <i>Eanthemata</i>		Varieties. H. zoster	880
Roseola	870	H. iris	881
Erythema	871	H. circinnatus	881
Varieties. Local	871	Order 4. <i>Bulle</i>	
Constitutional	872	Pemphigus, or pompholyx	883
Urticaria	874	Varieties	883
Varieties : local, acute, and chronic	874	Rupia	885
Order 2. <i>Hæmorrhagia</i>		Order 5. <i>Pustula</i>	
Purpura	876	Impetigo	886
Scorbutus	876	Varieties	887
Order 3. <i>Vesicula</i>		Porrigo, meaning of this term of Willan	887
Sudamina	876	Ecthyma	888
Miliaria	877	Order 6. <i>Papula</i>	
Eczema	877	Strophulus	889
Varieties. E. impetiginodes	878	Lichen	890

		PAGE
Varieties	891	Kelis, or keloid 918
Prurigo	892	Xanthoma, xanthelasma, or vitili-
Local prurigo	893	goidea 920
Order 7. <i>Squammæ</i> .		Order 9. <i>Macule</i> .
Pityriasis	894	Excess of pigment 921
Psoriasis	895	Addison's disease 921
Ichthyosis	897	Moles 922
Varieties	898	Want of pigment 922
Order 8. <i>Tubercula</i> .		Albinism 922
Acne	903	Vitiligo 922
A. simplex	903	Silver stain 922
A. indurata	903	
A. rosacea	904	Order 10. <i>Parasita</i> .
A. sebacea	904	Tinea 923
A. fuscum	906	T. tonsurans 923
Lupus	906	T. favosa or favus 924
Tubercular lupus	906	T. sycosis or mentagra 926
Strumous lupus	907	T. (or Pityriasis) versicolor 927
L. exedens	907	Relations of parasites of parasitic skin
Syphilitic lupus	908	diseases 928
Impetiginous or pustulo-papular		Relations between Herpes circinatus and
lupus	908	parasitic diseases 928
Erythematous lupus	910	Scabies 929
Elephantiasis Græcorum (leprosy)	913	
E. Arabum (Barbadoes leg)	915	Diseases of Hairs.
Framboesia, or yaws	918	Porrigio decalvans 930
		Plica polonica 931

LOCAL DISEASES OF THE SKIN.

By THOMAS SMITH, Esq.

Surgeon to St. Bartholomew's Hospital.

Revised by RICKMAN J. GODLEE, Esq.

Assistant Surgeon to University College Hospital.

Corns	932	Carbuncle	949
Varieties. Hard, fibrous, and soft	933	Seat of carbuncle	951
Treatment	934	Progress	951
		Treatment by incision	952
Bunions	936	" by caustic	953
		" expectant—pressure	953
Warts	938	Malignant or facial carbuncle	954
Varieties of warts	938		
Causes	939	Malignant Pustule or 'Charbon'	957
Progress and treatment	940	Treatment	959
Horns	941	Chilblain	960
Origin of horns	942	Its three kinds or degrees	960
Treatment	943	Diurnal exacerbations	961
		Usual situations	961
Boils	943	Treatment	961
Ordinary blind boil	943		
Blind boil	944	Diseases of the Nails.	
Cadaveric boils	945	Onychia maligna	962
Constitutional causes	945	Syphilitic onychia	966
Effects of boils	947	Psoriasis of the nails	966
Treatment	947	Ingrown toenail	968
		Evulsion of nail	964

DISEASES OF THE EYE.

CHAPTER I.

OPTICAL DEFECTS.

Refraction and Accommodation.—Emmetropia ; Ametropia (Myopia, Hypermetropia, Presbyopia, Astigmatism).

ASSUMING the reader to be acquainted with the general laws of optics, it will be convenient to begin with their application to the eye as an optical instrument, and then to pass to the consideration of those defects which interfere with its proper performance.

The eye may be compared to a camera obscura in which the sclerotic, lined by the choroid, represents the box with its blackened interior ; the iris corresponds to the perforated diaphragm which stops out the extreme peripheral rays of the incident cone of light ; the ocular media answer to the system of lenses which collects the rays, and the retina to the screen upon which are formed the images of external objects lying before the camera.

Refraction—The transparent media of the eye are the cornea, aqueous humour, lens, and vitreous humour. At each of their limiting surfaces all rays of light entering the eye (except such as coincide in direction with the optic axis) are refracted or bent from their previous direction, the chief refractions occurring at the anterior surface of the cornea, and the anterior and posterior surfaces of the lens. The purpose of these refractions is the collection of the rays in exact foci upon the retina, which is necessary for the production upon this membrane of a sharp image of an external object before the eye, an essential condition of distinct vision.

Refraction is a purely physical phenomenon ; it might equally occur in a dead eye, whilst its media still preserved their true forms and their structural integrity. By *refraction*, or *refraction of the eye*, is to be understood the sum of all the refractions at the several limiting surfaces of the ocular media, the eye being at rest. In the normally constructed eye, at rest, the posterior principal focus (or meeting point of parallel rays) is on the bacillary layer of the retina. For our purpose we may conceive as parallel all rays incident upon the eye from objects distant twenty feet or more from the eye, since such distances are so very great relatively to the smallness of the pupillary opening, that rays entering this from luminous points at such distances include so minute an angle that they do not sensibly diverge. Luminous points situated at such distances as twenty feet or more are, therefore, conventionally conceived as infinitely distant.

For the normally constructed eye, the posterior principal focus being on the bacillary layer of the retina, the furthest point of distinct sight, *punctum remotissimum*, r is situated at infinite distance. Such an eye is termed by Professor Donders *Emmetropic* ($\epsilon\mu\mu\epsilon\tau\rho\omicron\varsigma$, modum tenens, and $\omega\psi$, oculus) and its refractive condition is *Emmetropia*.

Deviations from Emmetropia, comprised under the term *Ametropia*, occur in two opposite directions. In one of these the posterior principal focus of the eye is in front of the retina, the effect of which is to restrict r to a finite distance, whence sensibly divergent rays fall upon the eye. An eye thus conditioned could analogously be

termed *Brachymetropic*, r being at some shorter distance in front of it than infinite, and the condition would be called *Brachymetropia*, familiarly known as *Myopia*.

In the other deviation from Emmetropia the posterior principal focus is behind the retina. The refraction of such an eye, at rest, is insufficient to collect parallel rays in exact foci upon the retina, and rays incident upon the eye in order to be collected in exact retinal foci must already converge before entering the eye. Here r is conceived to lie beyond the measure of infinite distance, and the condition was termed by Professor Donders *Hyperemmetropia*, in its contracted form *Hypermetropia*.

The position of the posterior principal focus in Emmetropia, and in the two forms of Ametropia, Myopia, and Hypermetropia, is shown in Figs. 1-3.

FIG. 1.—Emmetropic eye in a state of rest. Parallel rays, a, a , come to a focus on the retina at b . Rays from a near object, c , being divergent, tend towards a focus behind the retina, d . The act of accommodation, which consists in increased convexity of the lens, causes these divergent rays to converge to a focus at b .

FIG. 2.—Myopic eye; too long in its antero-posterior diameter. Parallel rays, before reaching the retina, come to a focus at b , then, crossing, they form on the retina circles of dispersion at b', b'' .

FIG. 3.—Hypermetropic eye; too short in its antero-posterior diameter. Parallel rays, tending towards a focus at b , form on the retina circles of dispersion at b', b'' . Divergent rays would tend towards a focus still more distant than b .

We have hitherto supposed the refraction of the eye to be equal in every meridian. This is not absolutely true; usually the refraction in the vertical meridian is stronger than that in the horizontal, owing to the radius of curvature of the cornea, in the former meridian being somewhat shorter. In Emmetropia this difference of refraction is so small that pencils of rays incident in these opposite meridians meet, if not with absolute exactitude, yet so very nearly at the same distance behind the common nodal point of the eye that the sharpness of the retinal image does not sensibly suffer. When, however, the refraction in any meridian differs by more than a minute quantity from that in the other meridians, the rays incident on that meridian do not meet in the same focal plane as those incident in other meridians, and the condition known as *Astigmatism* results. The difference of refraction may be one of excess or deficiency, so causing myopic and hypermetropic astigmatism. These may occur alone, refraction in other meridians being emmetropic; or in combination with

general myopia or hypermetropia, occasioning *compound astigmatism*; or, which is less frequent, both forms of astigmatism may be present, one meridian of the eye being myopic, and the opposite one hypermetropic, constituting *mixed astigmatism*.

Accommodation.—It has been mentioned that rays incident from a luminous point situated at a finite distance are divergent. It is evident that the refraction proper to unite in exact retinal foci rays incident on the eye from infinitely distant objects will not suffice to collect in exact foci on the retina divergent rays incident on the eye from nearer objects lying at finite distances.

To effect this the refraction of the eye must be changed; it must be increased proportionately to the greater divergence of the incident rays; in other words, to the nearness of the object desired to be seen distinctly. This change of the refraction of the eye for viewing nearer objects is termed *Accommodation*, less usually *Adaptation*, *Adjustment*.

It is a voluntary act, its mechanism being chiefly increased convexity of the anterior surface of the lens effected through the agency of the ciliary muscle.¹

For every eye there is a distance within which an object cannot be distinctly seen even with the utmost tension of accommodation, because the rays falling upon the eye from a luminous point within this distance diverge too strongly to be collected in exact foci upon the retina. A point placed at the shortest distance at which it can be distinctly seen is termed the nearest point, *punctum proximum*, p , of distinct vision. The amount of accommodative change of refraction which is possible between complete relaxation and the greatest tension of accommodation is called the *range* of accommodation. It is expressed by the power of a convex lens which imparts to the rays falling on the eye from p the direction of those incident upon it from r ; and this lens is given by the formula $\frac{1}{p} - \frac{1}{r} = \frac{1}{a}$, in which p is the measured distance of the nearest point of distinct vision from the common nodal point of the eye, r the furthest point, and a , the focal length of a convex lens conceived as superposed on that of the eye.

In early childhood p is very close to the eye, in the 12th year of life it is $2\frac{1}{2}$ inches distant, by the 25th year this distance has increased to 4 inches; at 40 it has become 8 inches, at 60 it exceeds 24 inches; in very advanced life it coincides with r , and may even be conceived as lying beyond infinite distance, the posterior principal focus of the eye in this case falling behind the retina.

When p has receded from the eye beyond 8 inches, it is found that occupation upon small and near objects, as needlework or books, especially by artificial light, becomes difficult, and the eye is then considered to be *Presbyopic*. It is evident that, with the recession of p from the eye, the range of accommodation (A) diminishes throughout life from childhood to old age. If numerical values are substituted for p , r , and a , then in the 12th year $\frac{1}{2\frac{1}{2}} - \frac{1}{0} = \frac{1}{2\frac{1}{2}} = A$, which is the range of accommodation. In other words, the change of accommodation which at this age the emmetropic eye effects in passing from complete relaxation to the greatest tension is equivalent to an increase of refraction, such as would be made by the addition to the eye of a convex lens of $2\frac{1}{2}$ inches focal length. At the 25th year a loss of A has been sustained equal to the difference between $\frac{1}{2\frac{1}{2}}$ and $\frac{1}{4}$; by the 40th year A has diminished to half of what it was in the 25th year; and when in old age p coincides with r , A wholly disappears.

The space between p and r is the region of accommodation. This is not to be confounded with range of accommodation, recently defined. The same range of accommodation may be found with very different regions of accommodation; thus with $p=8$ inches, and $r=\frac{1}{0}$; p at 4 inches, and r at 8 inches; p at 6 inches, and r

¹ For a full explanation of this the reader should consult any of the current text-books of physiology.

at 24 inches the range of accommodation, $A = \frac{1}{8}$, whilst the region of accommodation is in the first instance between 8 inches and infinity; in the second between 4 and 8 inches; and in the third example between 6 and 24 inches.

Hitherto accommodation has been considered with respect to one eye. When both are used it will be found that the proximate point of distinct sight p' is nearer than when one eye only was employed, for the intimate association of convergence of the visual axes with accommodation makes a higher tension of this possible when the eyes are strongly converged. There exists, therefore, a binocular proximate point of distinct vision p' , which is distinct from the monocular p . Further, whilst the distance of the object, and therefore the convergence of the eyes, continues unaltered, the object can still be distinctly seen when collecting and dispersing lenses of a certain power are placed before the eyes. As the effect of such lenses is to lessen and to increase the divergence of the rays incident from the object upon the eye, their addition is equivalent to the approach and the withdrawal of the object, and involves relaxation and increased tension of accommodation. Besides the monocular and binocular proximate points of distinct vision, p and p' , there is, therefore, for each degree of convergence of the eyes a relative proximate and remote point, p'' and r'' and range of accommodation.

The position of the proximate point of distinct vision p is easily ascertained with the wire optometer, which bears Von Gräfe's name, a small oblong metal frame across the opening of which are stretched several fine wires. It is moved from the greatest distance at which the wires are apparent gradually towards the patient, who is directed to endeavour to keep them distinctly in view, and to mention instantly where the slightest indistinctness occurs. This point is p , its distance from the eye is measured with a tape attached to the frame, or with a rule upon which the optometer is made to slide. This form of optometer gives satisfactory results with intelligent persons used to observe; but for the examination of the less intelligent, who not infrequently consider that they see the wires distinctly so long as they can count them, a single wire will be found a better test than a series of several wires. For artisans a thin edge, and for literary persons small print, are convenient tests.

For the determination of r , and also for testing the acuteness of sight (V), the scale of types devised by Snellen is largely used. For illiterate persons a scale of dots, such as those in Burckhardt's 'Internationale Sehproben,' may be substituted, but the results will scarcely be as accurate. The principle underlying Snellen's scale is that the letters are seen under an angle of 5° at the distance marked beneath them. If No. 20 in this scale is sharply seen at the distance of 20 feet, and the addition to the eye of a weak convex lens dims the test, r is conceived to be at infinite distance, the eye is emmetropic. If for the sharp definition of the test a concave lens of 20 inches focal length is required, r lies 20 inches before the eye, increased by the distance between its common nodal point and the lens. Again, if the test is sharply seen when a convex lens is placed before the eye, r is conceived as beyond infinite distance; it is a virtual point behind the eye towards which the rays incident from the test converge, and its distance from the common nodal point of the eye is given by the focal length of the strongest convex lens with which the test-object is distinctly defined, diminished by the interval between the lens and the ocular nodal point. Such determinations, however, have only an approximate value, since not infrequently in myopia, and generally in hypermetropia, the accommodation is not completely relaxed. When exactitude is desired, the ciliary muscle should be previously paralysed with atropine.

Trial Lenses and Spectacles.—For testing the refraction of the eye, and for selecting spectacles for treatment, trial lenses are indispensable. These are supplied by opticians in boxes containing sets of convex and concave lenses of spherical and of cylindrical curvatures, prisms, coloured glasses, diaphragms with narrow openings, stops, and one or more clip-frames in which the lenses and other apparatus can be placed for use.

Until very lately in this country, spectacle lenses were by most opticians and by practitioners in eye-diseases numbered according to their focal length expressed in inches, and the reciprocal of this expressed their power, which is inversely as the focal length. Thus Nos. 1, 2, 3, 4, &c. indicated a lens of 1, 2, 3, 4, &c. inches focal length, the dioptric power of which was as $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, &c.

Recently the French metre, called a *Dioptrie*, has been adopted by many practitioners abroad and by some at home as a basis of numeration. In this system the lenses are numbered according to their dioptric power, expressed in terms of the *dioptrie* D; thus a lens of 1 D, 2 D, 3 D, 4 D, &c. indicates a lens whose dioptric power is the sum of that of 1, 2, 3, 4 lenses, each of a power of a lens of 1 D. Facility of calculation in decimals, and the advantage of a universal basis of numeration, appear to be the chief recommendations of the system. In our article we shall still follow the old plan, principally because the *dioptrie* is not yet universally employed, and because it is often of more concern to the practitioner to know the focal length of a lens than its dioptric power.

The necessity of a proper adaptation of the spectacle frame to the figure of the face, and of a proper correspondence of the centre of the lenses and pupils, is so evident, that it would not be mentioned but for the frequent inattention to these matters.

Clinical determination and correction of Myopia, Hypermetropia, Presbyopia, and Astigmatism.

Myopia has been defined as the construction of eye in which the posterior principal focus lies in front of the retina, and therefore the remotest point of distinct sight (r) is situated at a finite distance in front of the eye. With the determination of r the presence and the degree of myopia are ascertained; and r is given by the focal length, expressed in inches, of the weakest concave glass which renders distinct the letters in the test-scale placed twenty feet off; in other words, by the focal length of the glass which imparts to the parallel rays incident from these letters upon the eye the direction of rays proceeding from a less distant point before the eye, upon which they would fall with just sufficient divergence to be collected by the refraction of the eye exactly upon its retina. This less distant point is the remotest point of distinct vision.

Popularly, near-sightedness comprises many imperfections of sight which have only this in common, that the book or needlework must be brought very near, and distant objects are very imperfectly perceived. Therefore not much value should be attached to the complaint of being near-sighted, but a book of test-types should be given to the supposed myope, and the maximum distances noted at which he can read the smaller types. If these distances are less than those at which the same types are read by emmetropic eyes, the supposed myope is next shown the scale of larger letters placed at the distance of twenty feet, and if he does not distinctly see these with the unaided eye, a series of concave glasses are successively held before it, and the weakest glass ascertained with which these letters are made distinct; if the focal length of this glass should be 12 inches, there is myopia of $\frac{1}{12}$, and r is 12 inches distant in front of the eye, augmented by the $\frac{1}{2}$ inch which intervenes between the optical centre of the glass and the common nodal point of the eye. This in the slighter degrees of myopia is of little moment, but in high degrees must be taken into account. In the slighter degrees of myopia this glass may be worn always, but in high degrees of myopia a weaker glass should be used for nearer objects than completely corrects the myopia. Thus, with myopia of $\frac{1}{6}$, a glass of $\frac{1}{6}$ may be given for reading music at 18 inches. In the highest degrees of myopia, as $\frac{1}{2}$ to $\frac{1}{4}$, glasses which do not completely neutralise the myopia will very often be preferred, as more comfortable even for infinitely distant objects.

In hypermetropia the posterior principal focus, as has been already explained, is behind the retina, so that even the parallel rays incident upon the eye from infinitely distant objects cannot be united upon the retina without an accommodative

effort, and such effort must be increased proportionately to the greater divergence of the incident rays as an object lies closer to the eye. Sustained occupation upon small or near objects, as reading or needlework, therefore soon causes fatigue; and it is this which usually compels hypermetropic subjects to seek advice. They very frequently come with the statement that they see well enough for a short time, but then the print or the needlework becomes confused, the letters or stitches seem to swim and to run together, and this more toward the close of the day than in the morning. When the distant test-scale is viewed through a convex lens which renders convergent the parallel rays incident upon it from the letters, these appear as clear or much clearer through the lens than when seen with the unaided eye. The ability to see distant objects distinctly through a convex lens establishes the presence of hypermetropia. The strongest convex lens with which the distant scale is clearly seen gives the amount of manifest hypermetropia. If now the accommodation be paralysed with a strong solution of atropine dropped into the eye at short intervals, several times, the letters in the distant test-scale will be clearly recognised through a much stronger convex glass than before. The reciprocal of the focal length of the glass expresses the total amount of hypermetropia, and the difference between this and the manifest hypermetropia ascertained before the employment of atropine is the amount of latent hypermetropia, *viz.* that which was masked by accommodative effort, which the hypermetropic was unable to suspend at will. In young persons it will be commonly sufficient to neutralise all the manifest hypermetropia; in other words, to allow the strongest glass through which, without the use of atropine, distant objects are clearly recognised, and such glasses may be constantly worn.

Presbyopia.—This, though not strictly a form of ametropia, since it is the natural condition of the emmetropic eye in advanced life, will be conveniently considered here. It has already been pointed out that throughout life, from childhood to old age, the proximate point (*p*) of distinct vision is constantly receding from the eye—with such recession a time arrives when occupation with small and near objects becomes difficult, especially by artificial light. There is difficulty in threading the needle; the book is held further off, and soon laid down; the eyes are quickly tired. It is found that these difficulties arise when *p* has receded to beyond eight inches from the eye. This distance has, therefore, been selected as the term at which presbyopia, *P*, begins. Its degree is given by the reciprocal of the focal length of the convex lens, the dioptric power of which brings back the actual proximate point *p*, ascertained by measurement with the optometer, to the arbitrary term 8 inches. Thus, supposing *p* is found to = 24 inches, then $\frac{1}{8} - \frac{1}{24} = \frac{1}{12}$. In which 12 inches is the focal length of the convex lens, which will bring back *p* to 8 inches, and $\frac{1}{12}$ the dioptric power, which expresses the degree of presbyopia, *P*.

The troubles incident to presbyopia are to be met by the use of convex spectacles. These, when only very slight degrees of presbyopia are present, should clear and sharpen the type, but not sensibly enlarge it. At first they will usually be found requisite only, or chiefly, at night; later, they will come into use by day, and somewhat stronger glasses be preferred at night. In advanced age, when senile tissue-deterioration has dulled the transparency of the media and blunted the sensitiveness of the retina, preference will be given to glasses which sensibly enlarge, and these may safely be allowed.

Astigmatism.—A simple and ready method of detecting astigmatism is to ascertain whether bars, each composed of two or three parallel lines, radiating from a centre like the spokes of a wheel, are all simultaneously seen with equal distinctness. Should one bar appear more distinct than the others, astigmatism is present. For less intelligent persons, unused to observe, a single bar of lines which can be turned round upon a disc like the hand of a clock is a preferable test. As this revolves, one position will be found in which it is seen distinctly, or less indistinctly than in other positions. The refraction of the eye is now taken with a spherical lens, in the meridian perpendicular to the less indistinct line; the bar is then rotated through 90°, and the refraction taken in the opposite meridian.

An example will make this more easily intelligible. A person with defective sight cannot recognise smaller letters than 50 in the test scale at 20 feet distance.

A weak spherical convex glass increases the indistinctness of the letters; a weak concave glass helps somewhat, but does not enable him to discern No. 30 type; this visual acuteness is expressed by $V = \frac{2}{3}$, and spherical glasses do not materially help, convex, distinctly reducing the acuteness. No general myopia or hypermetropia is present. On viewing the radiating bars, one is noticed in which the lines appear sharply defined; whilst, in the bar perpendicular to this, the lines appear confused or are quite unrecognisable, the bar itself appearing as a blurred band. A spherical concave lens, of 30 inches negative focal length, renders the horizontal bar as distinct as was previously the perpendicular bar. The vertical meridian of the eye refracts $\frac{1}{30}$ too strongly; there is myopia of $\frac{1}{30}$ in this meridian. A cylindrical glass of $\frac{1}{30}$ placed before the eye, with its axis coincident with the horizontal meridian of the eye, clears the vertical bar, and also clears the smaller types in the test-scale, increasing V to $\frac{2}{3}$. This glass may be constantly worn. If the vertical bar had required a concave spherical lens of $\frac{1}{30}$ to clear it, and the horizontal bar needed the addition of another lens of $\frac{1}{30}$ to make it also clear, the case would have been one of compound astigmatism, and required for its correction a spherical glass of $\frac{1}{30}$, with the addition of a cylinder of $\frac{1}{30}$, which is obtained by having one surface of the lens ground to a spherical curve of 30 inches, and the other to a cylindrical curve of 30 inches.

Substituting convex for concave lenses, this illustration holds good for hypermetropia. Again, if upon examination the vertical bar had required for its distinct perception a concave glass of $\frac{1}{30}$, and the horizontal bar a convex glass of $\frac{1}{30}$, mixed astigmatism is present, which requires for its correction a double cylinder of these strengths.

CHAPTER II.

EXAMINATION OF THE EYE.

Superficial Examination.

The Conjunctiva and Cornea.—The ocular portion of the former of these structures is open to the surgeon's observation, and, to explore the lining of the lower lid, it is only necessary to depress the tarsus with the point of the finger. It is often difficult to obtain a satisfactory view of the cornea in a child suffering from *Ophthalmia*, when light causes so much pain, that the child makes every effort to exclude it, by keeping the eyelids firmly pressed together, and even, in severe cases, thrusting his face against the pillow, or the dress of the attendant.

The surgeon does but waste his time who attempts to coax or parley with such a patient. He should sit and firmly fix between his knees the head of the child. The extreme tip of the forefinger, with a bit of rag twisted over it to prevent slipping, having been laid upon the middle of the upper tarsus, at the very edge of the lid, without any dragging of the skin, is to be steadily pushed upwards and backwards. In this way the greater part of the cornea is at once exposed; but, if the finger is allowed to drag the skin of the lid, the tarsal cartilage instantly becomes tilted over, and the swollen conjunctiva, bulging forwards, hides the eyeball from view. By a similar manœuvre the lower lid may be depressed; but this is not necessary in examining the cornea, for that part is always rolled upwards to seek the shelter of the upper lid.

Where there is much swelling a speculum may be employed, adapted, as regards width and strength of spring, to the small size of the palpebral fissure.

To expose the inner surface of the upper lid, it must be everted, as if the surgeon were in search of a foreign body. Whenever a patient complains of having had a fragment of anything blown into the eye, and a careful scrutiny of the edges of the tarsi, the fold of the lower lid, and the surface of the globe, has failed to reveal the cause of irritation, the upper lid should be turned out by placing a small pen, the extreme feather end of which is cut off, so as to leave a stem just thick enough to

resist bending, across it above the upper border of its cartilage; then, while the finger and thumb of the other hand grasp the eyelashes growing from the middle of the lid, the pen is pressed a little downwards, at the same moment that the lid is drawn first a little forwards, and then upwards; the tarsus will tilt and turn over, so as to expose its conjunctival surface. If, at the moment the turn is being given to the lid, the patient is told to look downwards, the eversion is much more readily accomplished.

Minute foreign bodies, which have fixed themselves beneath the upper lid, are usually found near its tarsal margin. It is when situated here that they cause such distress in the movements of the eyelid over the cornea. When lodged in the conjunctival sinus above the tarsal cartilage, they are liable to scarcely any displacement in winking, do not rub the cornea, and often cause very slight annoyance. They should be lightly picked off with the feather or nib of the pen used for effecting the eversion. A pen is not only more convenient than a probe, but it has the advantage of appearing less formidable to a timid patient.

The cornea, anterior chamber, iris, lens, and the more superficial part of the vitreous humour, can be more searchingly examined when illuminated by a pencil of light thrown obliquely upon them with a convex lens of short focal length than is possible without such aid. The parts under illumination may be advantageously viewed through a magnifier. In the examination of the cornea, the illuminating pencil is brought to a focus upon its surface, when any irregularities, unevennesses, and opacities become apparent by directly reflected light, or the pencil may be focussed on the iris and the cornea seen by light transmitted through it after reflection from the iris.

The lens cannot be fully seen until the pupil has been widely dilated with atropine; but, inasmuch as this dilatation alters the visual condition of the eye, all particulars as to the patient's range and distinctness of sight should be noted before the atropine is applied. Slight opacities may easily elude detection unless care is taken, particularly when very strong illumination is employed. In the lenses of old persons, internal reflections caused by differences in the refractive indices of the fibrous tissue and thin planar sheets produce under oblique illumination an opalescence which closely simulates actual opacity.

The contractility of the iris is tested by shading the eye with the hand for a second or two, and then quickly withdrawing it, so as to allow the light to fall suddenly upon the pupil, the other eye meantime being closed. The consensual action of the irides should next be examined, by observing how far light admitted to one eye influences the pupil of the other.

The separate examination of each eye is a very important point, for cases occur in which, while one eye is sound, the other is so utterly blind as to have lost all perception of light, yet the pupil of this blind eye will contract as soon as light is admitted to the sound one. An extensive adhesion between the edge of the pupil and the capsule of the lens (*Synechia posterior*) would at once attract notice; but, if any slight deviation from the healthy round form of the pupil exists, its margin must be carefully examined, to see if any very small adhesion be the cause of such irregularity. A very slight synechia often affords a valuable hint towards diagnosis, as proving that iritis must at some period or other have attacked the eye. Persistent traces of the fetal pupillary membrane may be distinguished from the adhesions due to acquired iritis by their attachment to the lesser circle of the iris and not to the margin of the pupil. Whenever the surgeon is in doubt as to the existence of adhesions, the application of atropine will determine the question.

It should ever be borne in mind that a dilated and inactive pupil by no means necessarily implies that the retina is diseased; nor an active pupil that the retina is sound.

The simple modes of examination hitherto mentioned have at all times been at the surgeon's command; I come now to consider the use of an instrument—the *Ophthalmoscope*—the invention of which has enabled us to explore those deeply-seated structures previously altogether beyond the range of observation.

It is now little more than thirty-five years ago since Cumming first demonstrated that by a certain arrangement of illumination the bottom of the healthy human eye could be rendered visible so far as to allow its brilliant reflex being seen. Failing to comprehend the cause of the blackness of the pupil under ordinary circumstances of illumination, he just missed making a great discovery. Six years later the solution of the phenomenon was given by Helmholtz. The blackness of the pupil had previously been ascribed to extinction by the choroid of the rays of light, which, having entered the eye, and traversed the retina, fell on this pigmented coat. Helmholtz showed it to be the necessary effect of refraction. Sufficient rays are reflected from the bottom of the eye to render visible the parts there situated; but since these reflected rays in emerging from the eye must traverse the same ocular media through which they passed in entering the eye, it is evident that they must undergo the same refraction which, as entering rays, they underwent, only in an opposite direction: the result of this is that the paths of the emerging and entering rays coincide, and the former will therefore return to the source whence, as incident rays, they originally started. From this it is evident that an observer cannot bring his eye into the path of the rays reflected from the bottom of another person's eye without by the same act intercepting the rays incident from the source of illumination upon this latter: and since the observer's eye cannot receive from the bottom of the other eye any rays except those which it originally sent to it (and under ordinary circumstances of illumination it sends none), the observer sees in the blackness of the pupil of the other eye merely the reproduction of the blackness of his own pupil.

When the eye under observation is not truly accommodated for the source of illumination, the rays reflected from the bottom of the eye will not all return to the point whence they originally proceeded, but they will form about this a dispersion circle, and if the observer bring his eye within the limits of this circle, it will receive some of the returning rays, and the pupil of the observed eye will appear to glow brightly. This is what occurs in Cumming's experiment. Having solved the cause of the blackness of the pupil, Helmholtz contrived a speculum which made it possible for the observer to bring his eye into the path of the returning rays reflected from the bottom of the eye under observation, without cutting off the rays incident on this from the source of illumination. Of this invention it may be said, without exaggeration, that it marked the beginning of exact diagnosis of the deeper diseases of the eye.

As invented by Helmholtz, the first speculum oculi, or ophthalmoscope, consisted of a reflector of superposed slips of plain glass, mounted in a frame placed obliquely upon one end of a short metal tube, the other end of which was countersunk for the reception of a lens. With this instrument Helmholtz was able to see the optic nerve and larger blood-vessels of the retina.

Its form being inconvenient, and its illuminating power relatively weak, this ophthalmoscope was early superseded by others. It would much exceed the scope of this article to notice the numerous modifications it has undergone. Those now most generally used are concave mirrors of silvered glass or metal, with a small central sight-hole; and an arrangement behind the mirror for the reception of one, or of a series of lenses in a revolving disc which can be brought in succession behind the aperture.

With any of these instruments the refraction and transparency of the ocular media, and coarse structural arrangements of the coats forming the posterior segment of the eyeball, may be ascertained.

Two methods of examination, termed the direct and the indirect, are employed.

In the direct method the parts themselves are viewed directly. Their virtual image, enlarged and erect, is behind the eye. That it is erect is easily ascertained by noticing that, when the observer makes slight movements from side to side, or up and down, the image appears to undergo displacement always in the same direction; and that it is a virtual image is rendered evident by the fact that its sharpness does not suffer when the observer approaches his eye towards the observed eye, until the

distance between them has become so small as to seriously interfere with efficient illumination.

When patient or surgeon is myopic, a neutralising lens should be placed behind the mirror; and when the examination is for the purpose of determining the refraction, concave and convex lenses will be required, the power of which will represent the degree of ametropia present.

The direct method is useful for the examination of the ocular media, or where a considerable enlargement is desired. Its disadvantage is the smallness of its field. An inconvenience attending its use is the necessity of the observer bringing his eye within a very short distance of that of the patient.

In the indirect method a collecting lens of short focal length is used with the mirror, and it is not the bottom of the patient's eye which is seen, but an inverted real image of it situated before the eye, at a distance from it which will vary with the refraction of the eye, the focal length of the collecting lens, and the distance between this and the eye.

The enlargement is less than by the direct method, but it can be increased by placing a second convex lens behind the mirror, which acts the part of the ocular in a compound microscope. The chief advantage of the indirect method is the large field it affords.

Before commencing a thorough examination of a case, it is necessary to dilate the pupil with atropine, unless it has become permanently dilated from disease. In many instances, however, where a glance at the optic nerve and the parts adjacent is all that is required, it is unnecessary to subject the patient to this inconvenience.

The observer and the patient sit face to face in a room from which daylight is excluded; the only source of illumination being a lamp, or, still better, a jet of gas issuing from a jointed tube, so that the flame can be placed higher or lower according to the height of the patient's head. The flame should be on a level with his eye, and just far enough behind it to prevent any of the direct rays falling on his cornea. The chimney surrounding the flame must be of transparent glass, and, if faintly tinged with blue, it will modify the red rays, and impart to them a whiteness nearly resembling that of ordinary daylight. The observer places the back of the mirror close to his own eye, so that he looks through the central aperture, and holds the instrument at such an angle that the reflected light from it falls into the patient's pupil. This is always very difficult for a beginner to accomplish; but a little practice soon makes it easy. He will know that he holds the instrument in the right position by seeing the pupil assume a brilliant reddish appearance.

Still holding the ophthalmoscope in the same position, where the indirect method is employed, he takes in the other hand a convex glass, of two inches or two inches and a half focus, and places it at about this distance in front of the cornea. If the fundus of the eye be properly illuminated, and the convex glass correctly placed, and the observer's eye be properly accommodated for the distance of the real inverted aerial image, some of the retinal vessels will now be distinctly seen. The observer is often confused by seeing a small bright image of the mirror reflected from the surface of the object-lens. This image can be got rid of by giving to the lens a slight inclination.

By turning the eye in various directions, every portion of the retina is successively brought under the view of the observer. The necessity for varying the position of the eye constitutes a great objection to the more complicated ophthalmoscopes, which are fixed to a table or other support; and some eyes are so unsteady, and so little under the patient's control, that the observer is obliged to follow their movements by slight changes in the position of the ophthalmoscope, which can only be effected when the instrument is held in the hand.

(Ophthalmoscopic Appearances of the Eye in a healthy state.

(Plate 1. figs. 1 and 2.)

In the heading of this section I use the word 'healthy' with a certain latitude of meaning; for, apart from any serious disease, the mere advance of age imprints

upon the internal tissues of the eye certain changes of appearance, which, although deviating from an ideal standard of perfect health, can hardly be termed morbid. At present, I wish to present to the reader merely a sketch of what he is to look for in an eye which fairly performs its functions as an organ of vision.

Optic Nerve and Retina.—Since the intraocular end of the optic nerve is not exactly in the axis of the eyeball, but slightly inwards from this, in order to bring it into view, the patient must direct the eye a little towards the nose, or whilst the patient looks straight before him, the examiner brings his own eye into a line which includes with the axis of the patient's eye an angle of about 15° at its outer side.

The figure of the nerve is a circular or slightly oval disc, with a small central depression where the nerve fibres are deflected on all sides, known as the physiological pit, and a gently elevated margin where the aggregated nerve bundles for the whole retina bend over the choroidal opening. With attention a double contour indicating the edges of the scleral and choroidal openings may be made out. The colour of the peripheral portion of the disc is a delicate greyish pink, whilst the central part is brighter and whiter, with a faint tinge of blue. This coloration is the combined effect of the blood in its vessels, the glistening connective substance of the lamina cribrosa, and the greyish nerve fibres. It is greatly influenced by the intensity of illumination. Our judgment of the colour of the optic nerve is greatly affected by the intensity of pigmentation of the choroid: thus where the choroid is very dark, as in swarthy persons, the optic nerve by contrast appears whiter, and where the choroid contains a minimum of pigment, as is usual in fair persons, the colour of the optic nerve does not so greatly differ from that of the surrounding fundus oculi.

The retinal artery and vein traverse the centre of the disc, or as commonly pierce it eccentrically, in which case they appear nearer its inner side. The number and arrangement of their large branches depend on the early division of the main trunks within the cylinder of the nerve, or their later division near the inner surface of the disc. The artery, distinguished from the vein by its smaller calibre and its brighter red or scarlet colour, very commonly first divides at the surface of the disc into an upper and a lower primary branch, which subdivide towards the periphery of the disc, and thence pass over the border of the nerve into the retina. The veins, which are larger than the arteries, and of a deeper red or crimson colour, usually leave the surface of the disc separately, and unite in a single trunk within the nerve. Besides these large branches, the disc is usually pierced by numerous small arterial and venous offsets, derived from the main trunks within the nerve before their final division.

The retinal vessels give very distinct images, and can be followed from the optic nerve forwards towards the periphery of the retina. The principal arterial branches divide dichotomously, and their course is straighter than that of the veins, which run tortuously and receive tributary veinlets at large angles. The upper and lower hemispheres of the retina each receives two or more large arterial and venous branches. Those which are distributed to the outer segment of the retina diverge as they approach the yellow spot, passing above and below it, so that this part is supplied by capillaries only.

In the largest vessels within the nerve-disc, under a sufficient enlargement and good illumination, a practised observer may recognise slight pulsations, more readily seen in the veins. These pulsations become conspicuous where the tension of the eyeball is heightened in disease, and also in some disorders of the circulation dependent on cardiac disease.

The living retina, though a sufficiently good reflector of light, is so transparent that its recognition demands some practice in the use of the ophthalmoscope. It is most easily recognised in eyes in which the choroid abounds in pigment, which damps the splendour of the sclerotic reflex, and prevents its overpowering the fainter retinal image. This appears in such eyes as a thin bluish haze overlying the choroid. The yellow spot, which lies at the posterior pole of the eyeball, has a circular or oval form often indicated by a bright ring. It is distinguished by a slight difference in the quality of its reflex, from that of the part of the fundus oculi around it, than which it is slightly duller, and by the greater intensity of the choroidal pigmentation.

Choroid.—The red colour of the fundus of the living eye, which first strikes the observer, is due to the coloration given by the choroid to the light which traverses it after reflection at the inner surface of the sclerotic. The tint is the combined effect of the blood in its vessels, and of the pigment which is contained in its epithelium, and in the branched cells which form so large a portion of its stroma. Thus a small amount of pigment imparts a bright, clear, red colour, with a slight orange tinge. In such a choroid the ciliary arteries may be traced from the neighbourhood of the optic nerve forwards towards the equator, and the vasa vorticosa form conspicuous objects. More pigment imparts a decided orange. This is most intense in the spaces between the larger veins, which appear as light red bands between the darker spaces (Plate III., fig. 1). A larger quantity of pigment gives an orange brown, and still more pigment imparts a deep brown colour tinged with violet. In the eyes of black races such intense coloration of the choroid entirely hides its blood-vessels.

CHAPTER III.

DISEASES OF THE CONJUNCTIVA AND SCLEROTIC.

(*Ophthalmia, Conjunctivitis.*)

INFLAMMATION of the conjunctiva, I need hardly say, accompanies many of the inflammatory processes originating in other tissues of the eyeball. In the present chapter I confine myself to those cases in which the inflammation originates in the conjunctiva, and is either limited to it, or spreads only to the sclerotic.

Inflammatory redness differs very remarkably in these two structures. It is on the inner surface of the lids, and at their point of junction with the globe, that the conjunctival vessels are largest, and their redness is most strongly marked; and the colour becomes paler as the vessels diminish in size on approaching the cornea. The sclerotic vessels, on the contrary, are most visible close to the cornea, around which they form a pink circle, known as the *sclerotic zone*—a very characteristic mark of several important forms of disease in the deep seated tissues of the eye. Even if the sclerotic be uniformly injected throughout its whole extent, this injection cannot be traced very far back from the edge of the cornea, because the redness soon becomes hidden beneath the fibrous insertions of the recti muscles. The vessels of the sclerotic are small, closely set together, and so interlaced with the proper fibres of the part that the individual trunks cannot be recognised; they merely produce the effect of a uniform tint of colour, nearly resembling that of carmine. The conjunctival vessels, for the most part, are plainly seen, and, except in that high stage of inflammation termed *chemosis*, they can be observed repeatedly to anastomose, so as to form a closely-set network.

Elaborate classifications of the various forms of *ophthalmia* are to be found in many of the systematic works on eye-diseases, but minute distinctions, however plausible they may look on paper, are of little or no use to the practitioner. In selecting a few heads, under which to group the varieties of *ophthalmia*, I have been guided by the very decided peculiarities which certain forms present, or by the marked difference in the treatment they require. Many of the slighter forms of conjunctival redness, not resulting from direct violence or the presence of foreign bodies, are due to atmospheric changes; and the cases described by authors under the name *simple ophthalmia* are, for the most part, mild cases of catarrhal inflammation. When the sclerotic also is affected, the term *rheumatic* is sometimes added; and Mackenzie uses the words '*catarrho-rheumatic*' to signify that both the conjunctiva and the sclerotic are inflamed, although the inflammation may be due to the mere external agency of cold, and not to the presence of rheumatic poison in the blood of the patient.

Congestion of the conjunctiva may also be due to overwork, especially by artificial light, and to strain of the eyes in ametropia, either in consequence of the omission to wear spectacles, or of the use of improper spectacles.

Slight attacks of redness of the conjunctiva are commonly attended with only trifling uneasiness. The enlarged vessels, projecting above the level of the membrane, suggest to the patient the notion of foreign bodies, sand or dust, between the lids and the globe. But in other instances, where the redness is very trifling, the pain is of a neuralgic character, and it is for the irritation existing in the ophthalmic division of the fifth nerve that the patient seeks medical aid. It is important for the practitioner to remember that in such cases the suffering may be really severe, although there is far less appearance of inflammation than in other cases where pain can hardly be said to exist.

Whenever a case of ophthalmia is seen for the first time, the margins of the lids and the puncta lacrymalia should be carefully explored, as a few irregular eyelashes, or even a single eyelash, lodged in one of the puncta, may be causing the irritation.

It sometimes happens that a foreign body, lodged under the upper lid, sets up a considerable amount of ophthalmia, and yet the patient is not aware of any such cause of irritation being present. It is almost invariably found within a line or two of the tarsal margin.

After its removal the application of a piece of linen, dipped in iced water, usually soon relieves all inconvenience.

When the surgeon has satisfied himself that the redness of the conjunctiva is not caused or kept up by any mechanical irritation, he is not at once to prescribe a lotion or drops as a mere matter of routine. I shall hereafter have occasion to speak of the invaluable properties of a local stimulant in cases of true *catarrhal ophthalmia*; but at present I am considering those varying forms of conjunctival redness which are described by most writers under the name of *simple ophthalmia*. It is the surgeon's business to note well the general aspect of the patient: to ascertain what is faulty in respect of digestion, general nervous power, condition of the circulation, whether the ophthalmia can be traced to over-use of the eyes, exposure to irritating or vitiated air, want of exercise, excess in the use of stimulants, tobacco, &c.; in short, a rapid survey is to be taken of whatever is faulty in the patient's general health, and, in most cases, when this has been done, and the proper medical and dietetic means have been taken to correct what is amiss, the ophthalmia is already in a fair way of being cured.

As a rule, local congestion of the conjunctival vessels is met with in feeble and languid patients, who require tonics—iron, or quinine, or mineral acids, and a corresponding plan of diet. Of course there are many cases in which an excess of stimulants, and general over-feeding, have disturbed the due balance of the patient's circulation, and where a restricted and well-regulated diet is absolutely essential. But even in such cases a careful and moderate use of tonics is often necessary. What I wish to guard my readers against is the habit, which has been handed down to us from early times, of regarding all inflammations of the eye as necessarily to be treated by depletion, leeches, and low diet. The very reverse of this is the truth. The popular notion that a leech or two to the temples, and a purgative, must needs cut short an attack of inflammation in the eye is shared by only too many of the old school of practitioners. In young children especially such treatment is most mischievous. From the age of one or two years up to puberty, ulceration of the cornea is what we have most to fear, and this is sometimes attended with so slight a degree of redness of the conjunctiva and sclerotic, that it is important for the surgeon to be aware of this fact, and not to overlook slight attacks of ophthalmia in such subjects, but in every case to look carefully to the condition of the cornea.

While I so strongly insist on the great importance of general treatment in ophthalmia, I by no means exclude the use of local remedies. Where much intolerance of light exists, a small blister to the temple, or the application of tincture of iodine to the skin of the upper lid, will often afford great and immediate relief. Bathing the eyes night and morning with warm water is of great use in some

irritable patients; while in other cases the use of cold water is indicated. Those persons especially who have induced a congested state of the conjunctival vessels by prolonged exposure to artificial light, are often greatly relieved by a plentiful sluicing of the closed lids with cold water night and morning. Where there is agglutination of the lids during sleep, a little vaseline may be smeared on the eyelashes at bedtime. Weak solutions of acetate of lead or alum, or zinc-sulphate ($\frac{1}{2}$ grain to 1 grain to an ounce of distilled water) are useful in chronic cases; but they should be used sparingly, and never for too long a time. After a few days they should be left off, and the part allowed to recover its natural tone, the stimulant being resumed if necessary; but it should never be uninterruptedly continued for weeks or even months, as patients are only too fond of doing.

There are certain forms of ophthalmia which present such distinctive characteristics that they are very properly known by special names. Such are the *Catarrhal*, the *Purulent* (including the *Infantile* and the *Gonorrhœal* forms), the *Pustular*, and the *Chronic*. The disease commonly termed *Scrofulous Ophthalmia* should rather be classed among the diseases of the cornea; and the same may be said of the *Exanthematous* ophthalmia of authors; for it is the cornea which chiefly suffers, either by ulceration or sloughing, in consequence of the low state of vitality following the various forms of exanthematous disease. The term chronic, although of course applicable to any slow and protracted form of disease, when applied to ophthalmia is usually understood to mean an affection of the palpebral conjunctiva, the caruncle and semilunar fold, and the margin of the lids, which is either developed as an independent disease, or remains as a sequela of an acute attack of catarrhal or purulent inflammation.

CATARRHAL OPHTHALMIA.

This is commonly caused by exposure to draughts of cold air, but it is by no means limited to the cold season of the year. It frequently attacks large numbers of persons during the extreme heat of July or August, especially if, as often happens, an east wind prevails at the same time.

A well-marked case of catarrhal ophthalmia presents the following appearances: the cornea is quite clear, and vision is unimpaired, or only occasionally obstructed by the passage of thickened mucus across the area of the pupil. The conjunctiva of the lids is redder than natural, and the injection is particularly marked at the point of reflection of the conjunctiva from the lower lid to the globe. The semilunar fold and caruncle are red and much swollen, especially the former, and this enlargement of the semilunar fold often remains long after all other traces of the ophthalmia have subsided. The surface of the globe presents a network of vessels which gradually becomes less marked as it approaches the cornea. In some cases the sclerotic is involved, and then the peculiar pink zone is seen reaching close up to the margin of the cornea.

A peculiar characteristic of true catarrhal ophthalmia is the existence of numerous red blotches at various parts of the network of vessels, caused by some of these having given way and allowed their blood to become extravasated. The extravasations vary much in size; some are as small as a pin's head, others almost equal the breadth of the cornea.

At the commencement of the attack there is little increase of secretion; subsequently, mucous secretion sets in, which in some cases becomes so profuse as to make the surgeon suspect that the case may be one of true purulent ophthalmia.

There is usually no acute pain in common catarrhal inflammation; but a sense of weight and stiffness in the lids, and, as the disease advances, the enlargement of the vessels suggests to the patient the notion of sand or some other foreign substance between the lids and the globe.

When the sclerotic is much involved, there is usually intolerance of light, and much secretion of tears, and pain either of a dull aching or of an acute darting character. The upper lid, too, frequently becomes œdematous in cases of this mixed kind of sclerotic and conjunctival inflammation, and the infiltration of the subcon-

junctival cellular tissue raises the conjunctiva above the level of the cornea, so as even sometimes to overlap its margin. This elevated condition of the inflamed conjunctiva is termed *Chemosis*.

I need hardly say that a patient who is the subject of catarrhal ophthalmia is frequently disordered in general health, with confined bowels and disturbed digestive functions, and may require appropriate treatment by internal medicines; but very often the ophthalmia comes on without any general ailment, and seems a purely local affection, even limiting itself in some instances to one eye.

Treatment.—When the ophthalmia is unattended with constitutional disturbance, and is confined to the conjunctiva, the local application of nitrate of silver in solution may be regarded almost as a specific. It should be used in the proportion of two grains to the ounce of distilled water, and dropped upon the surface of the eye twice or thrice a day, the conjunctiva being cleansed, by bathing it with warm water, before each application of the drops. At bedtime the eyelashes should be anointed with a little vaseline. Care must be taken not to continue the use of the drops too long, lest the conjunctiva should become bronzed, on which account zinc sulphate is preferable. After being used for a week, they may be omitted for a couple of days, and then resumed as before, if the inflammation appears unsubdued; but often it will be sufficient, after a week's application as above described, to use the drops for a few days longer once a day. In uncomplicated cases, ten days or a fortnight will suffice for the cure; but, if the disease spreads to the sclerotic and cornea, the nitrate of silver must be omitted. The caruncle and semilunar fold are the last to recover their healthy condition after an attack of catarrhal ophthalmia. I have said that the treatment by nitrate of silver is to be adopted when the inflammation is *limited to the conjunctiva*: and it is from want of attention to this point that so much mischief is constantly done. Whenever the sclerotic is much inflamed, and, still more, whenever the cornea is in the least degree implicated, nitrate of silver does nothing but harm.

PHLYCTÆNULAR OR PUSTULAR OPHTHALMIA.

This is a very common form of ophthalmia, especially among children and young persons. It is characterised by little reddish elevations on the conjunctiva, close to the edge of the cornea, each surrounded by a plexus of blood-vessels. The centre of the little elevations is less vascular, and therefore whiter, than the base, and hence their appearance is a good deal like that of a pustule. When only one or two of these so-called phlyctænules are present, they are usually found upon the equator of the eyeball; but sometimes they are more numerous, and almost surround the cornea. Two forms are distinguishable, one in which the phlyctænules are attended with little pain, or intolerance of light, unless the sclerotic be also inflamed; another marked by great intolerance of light, pain, lachrymation, and spasm of eyelids.

Unless there be some derangement of the general health, the treatment of pustular ophthalmia is very simple, but relapses are frequent. When there is little or no intolerance of light, weak astringent solutions of one of the metallic salts, as zinc sulphate or alum, are useful; they should be dropped into the eye twice a day; but in neurotic cases, where intolerance of light is a conspicuous feature, atropine may be advantageously combined with the astringent drop.

Some practitioners attach great value to the local application of calomel in these affections. The calomel, which should be very finely powdered, is to be jerked on to the surface of the eye from a small camel's-hair brush. Others esteem highly an ointment prepared by thoroughly mixing the amorphous yellow mercurial oxide with vaseline in the proportion of gr. xxx. of the former to ʒj of the latter. Neither should be used whilst there is much vascularity, light-shyness, or lachrymation. If, as often occurs, the overflowing tears scald the skin of the eyelids and cheek, these should be anointed with a small quantity of vaseline, or the benzoated zinc oxide ointment (Ph. B.)

The health is usually deranged. Children with phlyctænular ophthalmia are usually feeble, often convalescent from some severe illness. A general tonic treatment

is therefore desirable. Cod-liver oil and iron are most useful. The intense intolerance of light often leads to the child being secluded in a close dark room, and if taken out, its eyes, and sometimes the whole head, are enveloped in wraps. This has the injurious tendency of making such patients still more weakly, and of fostering the intolerance of light. The room should not be very dark; daily outdoor exercise when the weather is favourable should be enjoined; all wraps should be removed from the eyes; a narrow shade standing straight off from the forehead will give all necessary protection.

PURULENT OPHTHALMIA.

(*Suppurative Ophthalmia; Ophthalmoblenorrhœa; Conjunctivitis puro-mucosa; Ophthalmia contagiosa; Egyptian Ophthalmia; Ophthalmia bellica; Military Ophthalmia.*)

On arriving at the consideration of this form of ophthalmia, we must no longer confine our attention to the conjunctiva; for, although it is in this tissue that the disease commences, it derives all its importance from the fact that the cornea is liable to become involved. Much has been written upon the essential differences subsisting between the common purulent ophthalmia of adults, that affecting infants, the Egyptian, and the gonorrhœal ophthalmia; but these various forms, in certain stages of their progress, often resemble each other very closely, so that a severe case of common purulent ophthalmia cannot be distinguished from one of gonorrhœal origin: and the purulent secretion from the eye of an infant suffering from *ophthalmia neonatorum*, if applied to the eye of an adult, may set up all the phenomena of the truly gonorrhœal form. We must not expect, therefore, to be able in every instance to say with certainty, the first time a patient comes before us, 'This is simple purulent ophthalmia;' or, 'This is of gonorrhœal origin;' we must wait until we have had time to watch the progress of the case.

If a patient presents himself in an early stage of purulent ophthalmia, we may, as I have said, be unable to distinguish the disease from the simple catarrhal form; but should the purulent ophthalmia have reached its height, we should find the following appearances.

The patient is generally pale and depressed; the lids are of a dull red, inclining to purple; they are swollen and œdematous, often to such an extent as to prevent the patient separating their margins in the smallest degree. When the surgeon draws them apart, thick yellow secretion oozes from the conjunctival surface, and if allowed to dry, forms a crust, which almost hides the eyelashes from view. The inability to open the eyes very naturally induces the patient to believe that he is blind, and this belief tends still further to depress him both in body and mind. To separate the lids, to cleanse the cornea from the secretion which overspreads it, and thus to give the patient a glimpse of surrounding objects, is often the best means of raising his general powers.

In a case of extreme inflammation such as now being described, the conjunctiva covering the globe is reddened, infiltrated with serum, and raised to a considerable extent above the surface of the sclerotic. This is especially the case immediately around the cornea, the conjunctiva being thrown up into a wall which overlaps the corneal margin. This raised condition of the inflamed conjunctiva constitutes what is termed *chemosis*, a very characteristic mark in this and other forms of severe inflammation. In exploring the surface of the cornea, the surgeon should not content himself with merely cleansing it from secretion by means of a bit of wetted lint or sponge; but with a probe or little spatula he should carefully lift up the overlapping portion of the chemosis, in search of any hidden ulcer; for it is at the extreme edge of the cornea that the ulceration set in, which may eventually go on to perforation.

The milder cases of purulent ophthalmia stop short of the ulcerative stage; and under appropriate treatment the puriform secretion ceases, the conjunctiva gradually loses its unnatural vascularity, and regains its healthy aspect.

The severer cases terminate either in *ulceration* or *slough* of the cornea. The

ulceration usually begins, as I have said, at the corneal margin, and as it extends assumes the form of a more or less deep crescentic groove. Then the ulcer perforates the cornea at some point, and a portion of iris prolapses, producing the appearance of a small dark-coloured nodule at the bottom of the ulcer.

Of course any protrusion of the iris must cause deformity of the pupil, which becomes pear-shaped, oval, or reduced to a narrow slit, in proportion to the amount of iris which has escaped through the ulcer. Sometimes the ulceration spreads as a deep groove quite around the margin of the cornea, so as to isolate its central portion, which stands out in relief, cloudy or wholly opaque. Eventually this central portion becomes involved in the ulcerative process, and then the whole cornea becomes thinned so as to yield to the pressure of the contents of the globe, and forms a bulging mass made up of the remains of the corneal tissue, between the fibres of which dark-coloured portions of exposed iris protrude. At a later period the surface becomes traversed by ramifying blood-vessels. This wholesale destruction of the cornea, however, rarely occurs except in cases of gonorrhoeal inflammation. Sometimes purulent ophthalmia, instead of inducing ulceration, ends in *sloughing*. In that case the chemosed conjunctiva encroaches a good deal upon the surface of the cornea; the latter becomes hazy, then opaque and yellowish, and quite dull on the surface; at last it looks almost like a piece of wash-leather, then softens and comes away in shreds; the whole iris bulges forwards, and becomes coated with a fibrous exudation, which eventually transforms the part into a *staphyloma*.

Purulent ophthalmia can undoubtedly be transferred from one eye to another by contact with the secretion. Patients therefore should be cautioned on this point, as also their nurses or attendants. It seems probable that in hot countries, where this ophthalmia is very prevalent, the flies act as propagators of the disease. The dust also of those countries, by keeping the conjunctiva in a state of chronic irritation, no doubt predisposes to the attack. In England the disease, like the common catarrhal form, is, I think, most frequent during the extreme heat which sometimes visits us in July or August, if it be attended, as is often the case, with an east wind.

Treatment.—Although the more rational practice of the present day has effected a vast reform in the treatment of so-called inflammatory diseases, both internal and external, the force of old prejudice and habit has, to a great extent, prevented medical men from applying the same reasoning and common sense to the treatment of eye-diseases which they apply to those of other organs of the body. And, indeed, if a practitioner, unaccustomed to meet with ophthalmic cases, turns in his difficulty to many a work of high authority, he finds such a system of depletion recommended for purulent ophthalmia as is positively frightful.

Purulent ophthalmia, in its severe form, is usually met with in patients who are irritable, pale, and depressed; depletion is therefore inadmissible.

If the patient's bowels have been well relieved, the first requisite is usually a narcotic at bedtime. I almost always give tincture of hyoscyamus, \mathfrak{mxxv} , or 3ss., or even 3j in camphor-mixture, unless the patient has been habituated to the use of opium, when a moderate dose of that drug may be preferable. It is not easy to lay down positive rules for diet, but it should be such as is best calculated to keep the patient's vital powers to the level of ordinary health; as much of plain nutritious food being taken as the stomach can digest, and just such an amount of stimulants as will aid digestion, and maintain the due vigour of the circulation. Quinine is almost always useful in suitable doses. In short, ulceration and sloughing of the cornea should be combated or guarded against, just on the same principles as those destructive processes would be combated in any other tissue of the body. To a delicate, ill-fed, over-worked woman, attacked with acute purulent ophthalmia, it may be necessary, in addition to a little beer at her dinner, to order a glass of wine twice or thrice a day. To a person in a comfortable position in life, the ordinary amount of stimulants may be amply sufficient, while, with one habitually intemperate a considerable diminution of the accustomed quantity may really effect the desired object, by avoiding that after-depression of the nervous system which invariably follows over-indulgence in drink.

The local treatment of purulent ophthalmia consists in the frequent employment of astringents, such as alum, nitrate of silver, or tannin, dissolved in distilled water. The alum may be used in the proportion of four grains to the ounce of distilled water, dropped into the eye, every hour during the day, and as often during the night as is compatible with the patient's rest. Where the surface of the globe can be well exposed by drawing down the lower lid, it may suffice to squeeze the lotion over it from the rag or a fine sponge. If there be so much swelling of the lids as to make it impossible to expose the surface of the globe, the lotion must be injected beneath the lids with a syringe, first throwing in a little warm water to clear away the discharge. As the case improves, the lotion may be used less frequently, every two or three hours. If nitrate of silver be employed, it should be in the proportion of three or four grains to the ounce, and be dropped upon the surface of the globe three or four times a day, after syringing away the discharge with a little warm water. Or the surface of the conjunctiva may be brushed once a day with a solution of silver nitrate of the strength of ss v. to ʒj of water. Tannin dissolved in distilled water may be used as a substitute for the alum. Strong solutions of these astringents should be used at longer, weaker at shorter intervals. In some severe cases which assume the violence of the gonorrhœal form, ulceration rapidly extends along the edge of the cornea—usually the lower edge—in the form of a deep crescentic groove. Unless speedily arrested, it penetrates the thickness of the cornea, and if the opening into the anterior chamber be large, so much of the iris may prolapse as greatly to diminish, or wholly to annihilate, the pupillary aperture. In such cases it is sometimes possible to check the spread of the ulcer by rapidly passing over its entire surface a fine point of nitrate of silver. A fine brush dipped in a gr. x. to ʒj solution of the salt is usually the best means of application.

I need hardly allude to the great importance of pure air in the disease now under our notice. In fine weather it is not necessary, even during the acute stage, wholly to confine the patient to the house: and when the ulceration is arrested, and the purulent discharge has ceased, careful and judicious change of air will tend more than anything else to remove the chronic ophthalmia, which is otherwise apt to linger on for a long period.

GONORRHOËAL OPHTHALMIA.

This disease is essentially the same in character as the preceding; but it is far more severe and destructive. It is caused by gonorrhœal matter coming in contact with the conjunctiva; and among the more ignorant classes it is sometimes the result of a very prevalent vulgar error—that a sovereign remedy for sore eyes is to bathe them in the patient's own urine.

I know of no symptom by which we can positively distinguish ordinary purulent ophthalmia from the gonorrhœal form, provided the two diseases are seen at an early stage. Many authors speak of gonorrhœal ophthalmia as almost invariably confining itself to one eye; but this is certainly not the case; and I could relate many instances in which both eyes were attacked within a few days of each other. Indeed, it seems strange that this is not the rule rather than the exception.

Gonorrhœal, like ordinary purulent, ophthalmia begins with redness of the conjunctiva, and a sensation of sand beneath the lids. After a few hours muco-purulent discharge sets in, and the ocular portion of the conjunctiva becomes infiltrated with serum. This thickening rapidly increases and forms a *chemosis*, which is always a very marked symptom in gonorrhœal cases. At the same time the lids become red, and so much swollen that the patient can separate them to only a very slight extent. The cornea becomes hazy; and at this stage an ulcer is almost certain to be found at its margin. Sometimes ulceration begins while the rest of the cornea is still clear; and in that case some care is necessary to detect the loss of substance. A thorough examination of an eye at this stage of the disease cannot be made without the aid of the wire speculum, which prevents the swollen conjunctiva of the lids from bulging over and hiding the cornea. If the margin of the cornea be overlapped by chemosis,

a probe or little spatula should be used to hold it aside, while the surface of the extreme edge of the cornea is wiped perfectly clean with a bit of wetted lint or rag.

Ulceration first attacks the extreme edge of the cornea, and extends in a crescentic form until a considerable portion of the cornea has been cut off from its nutritive supply, and then of course it loses its vitality. In some cases I have seen the ulceration extend all round the corneal margin; and then the central isolated portion, having previously become opaque, has rapidly assumed a softened pulpy appearance, and come away in shreds. The chemosis, which has been so much dreaded as the active agent in the destruction of the cornea, is formed by the infiltration of serum from the overloaded blood-vessels into the subconjunctival cellular tissue.

Patients affected with gonorrhoeal ophthalmia are almost always in a state of depression, with weak pulse and deranged digestion. This condition is partly due to the local disease itself, and partly to the distress of mind caused by the fear of impending blindness. It seems extraordinary that surgeons of eminence in times past can have been so far misled by theoretical notions about 'inflammation' as to have overlooked the general condition of these patients, and to have treated them by frightful bleedings, mercury carried to salivation, and other depressing means.

In speaking of purulent ophthalmia I have anticipated the treatment of the gonorrhoeal form. It is quite impossible to lay down positive rules as applicable to all cases. Each case becomes a study in itself, and according to the patient's constitution, habits, station of life, and previous treatment, must the surgeon modify his plan. To maintain the digestive functions, to administer suitable quantities of nourishment, to sustain the circulation at a proper point of vigour, neither unnaturally exciting it to hurried action, nor allowing it to flag, and so lead to local congestion of blood, and consequent deterioration of tissues—to secure as far as possible pure air at an equable temperature, to soothe the nervous system, and promote sleep by such mild narcotics as shall not confine the bowels or induce subsequent depression—such is the outline of the general treatment to be pursued.

The local applications I have already indicated, only I would lay still greater stress, in cases of gonorrhoeal ophthalmia, upon the utility of nitrate of silver, applied in substance to the conjunctiva and to the surface and edges of the crescentic ulcer. Unless this application be made with great care and neatness of hand, it may do more harm than good. A stick of nitrate of silver can hardly be pointed so sharply as to answer the purpose, and a brush is to be preferred. The lids being held apart with a wire speculum, and the edge of the cornea having been wiped clean, the brush charged with the solution of silver-nitrate is to be lightly passed over the whole surface. This application may require to be repeated upon the following day, but should not be persevered in after the ulceration has ceased to spread, and the puriform character of the discharge has ceased. In the intervals astringent injections should be frequently used. The continuous application of finely broken ice in a small caoutchouc bag is often of great service.

Where one eye only is affected the utmost caution should be observed to protect the other eye from infection. It may be covered with a carefully adjusted compress, or with a watchglass, the circumference of which is secured to the skin around the orbit with a circle of adhesive plaster. Where the chemosis is very great, it has been advised to divide the outer commissure of the eyelids for the purpose of lessening pressure. The writer has never found this necessary, and would prefer the old method of scarifying the oedematous conjunctiva.

In spite of all our efforts and care, it must frequently happen that cases of gonorrhoeal ophthalmia terminate in loss of sight. For the disease often occurs in unhealthy subjects, weakened by intemperance and debauchery, and who, before they apply to a regular practitioner, have probably been in the hands of quacks, whose only remedy is mercury. Still, when we consider of what immense importance it may be to retain even a small portion of the cornea in a transparent condition—thereby enabling the surgeon at some future time to make an artificial pupil, and so rescue the patient from blindness—we ought never to give up a case of gonorrhoeal ophthalmia so long as any portion of one cornea retains its vitality.

GRANULAR CONJUNCTIVA.

(Granular^s Lids; Trachoma.)

One of the most serious sequelæ of purulent ophthalmia, whether of the simple or the gonorrhœal form, is that condition of the conjunctiva termed 'granular.' During the progress of purulent ophthalmia, the palpebral conjunctiva, when cleansed from secretion, appears villous; and, after the purulent discharge has ceased, this condition of the membrane goes on increasing, until its surface resembles that of a granulating ulcer. The so-called 'granulations,' however, are in reality the follicles and papillæ of the conjunctiva, enlarged by inflammatory deposits. The firmness and solidity of these 'granulations' vary much in different subjects. When hard, and of considerable size, they cause irritability and blinking of the lids, and lacrymation, and after a time the cornea, especially its upper half, becomes hazy, and is traversed by numerous large vessels forming in some cases a complete network, and giving an almost fleshy aspect to the part (*pannus*).

Treatment.—The granulations were long since recognised as causing by their friction the chronic inflammation and vascularity of the cornea; and accordingly, a great variety of plans have at various times been adopted for removing the granulations and restoring smoothness to the palpebral conjunctiva. Complete excision with the knife or scissors, the rapid action of escharotics, and the more gradual wasting by means of astringents, have all in turn been employed against granular lids.

Effectually to cut away the granulations requires such extensive removal of the palpebral conjunctiva as is likely to induce permanent curving of the tarsus and consequent entropion; and the same result may follow the free employment of nitrate of silver. The ordinary astringent lotions of alum, tannin, &c., are powerless in the more severe cases. I have seen much benefit from the acetate of lead, applied by dusting it, in fine powder, over the everted lid. This causes a good deal of pain at the time, but afterwards gives decided relief, apparently by mechanically filling up the interstices of the elevations, and so producing a smooth surface for the eyeball to move upon. The salt as it slowly dissolves, seems also to exert an astringent effect upon the vessels of the enlarged follicles and papillæ, and so to diminish their bulk. But the most effectual means I have ever tried for removing granulations is the undiluted liquor potassæ, applied by dabbing it upon the everted lids, on which it seems to act by chemically saponifying and dissolving away the hypertrophied tissue. The application may be repeated at intervals of a few days; and six or seven weeks of this treatment will sometimes suffice to remove the granulations, and, at the same time, to restore a considerable degree of clearness to the cornea; or the everted eyelids may be brushed with a strong solution of silver nitrate, grains x. to ℥j, the excess being immediately washed off with a current of tepid water in which a little sodium chloride has been dissolved, or the granulations may be rubbed with a smooth crystal of copper sulphate. This should be repeated at intervals of three or four days.

But, every now and then, cases are met with in which the cornea is so opaque, and so traversed by large blood-vessels, as to prevent useful vision, even when the granular state of the lids has been almost subdued. Such instances of opaque and vascular cornea follow severe purulent ophthalmia, especially the form so common in the East, and known to us as Egyptian ophthalmia. Cases of almost equal opacity are met with at our London hospitals among the more destitute Irish patients. It appears that a very severe form of purulent ophthalmia is sometimes epidemic in certain districts of Ireland, rivalling in virulence the disease of tropical countries.¹

Patients who have been a long time suffering from granular lids in a severe form are almost invariably of poor health; often reduced by the violent courses of medicine

¹ Power, in a pamphlet on the Egyptian Ophthalmia, published in 1803, describes a species of the same disease as being 'frequently prevalent among the Irish peasantry, and considered by them to be infectious.' See also a paper by Wilde in the *London Journal of Medical Science*, vol. iii. 1851.

they have undergone, and with the eyes in an irritable condition from long-continued use of caustic applications. To place such patients, if possible, in a pure and bracing air, and to improve their general health by suitable tonics, will be the first indications for treatment. In this way considerable improvement may be induced both in the condition of the lids and of the cornea; but there will still remain certain inveterate cases, incurable by any ordinary treatment, either local or general. They usually present a granular condition of the palpebral conjunctiva; this, however, may have been got rid of, or greatly subdued, by treatment: the characteristic sign, which makes the disease so formidable, is the haziness and vascularity of the cornea.

We will suppose a case in which the granular condition of the lids has been partially or wholly cured, and the general health restored: but where, after exhausting every resource of his art, the surgeon still finds the patient's corneæ permanently opaque, and traversed in all directions by vessels, vision being limited to the mere recognition of large objects. There may be every reason to believe that the tissues of the eye posterior to the cornea still remain healthy, and yet the condition of the latter destroys all hope of good vision being regained.

For such desperate cases a seemingly desperate remedy—inoculation—has been proposed, consisting in the production of a fresh attack of purulent ophthalmia by applying to the conjunctiva some morbid secretion from the eye of a patient suffering under the acute form of that disease.

This treatment was extensively tried in Germany several years ago, but seems to have fallen into disuse. Its advocates asserted that purulent ophthalmia, thus produced in an eye which had previously undergone the disease, would cause a wasting of the vessels overspreading the cornea, and ultimately restore its transparency. There seemed however a great risk of the second attack proving as severe as the first, and ending in destructive ulceration of the cornea; and the fact of the inoculation serving to keep up and perpetuate a dangerous and contagious disease, also operated with many surgeons as a reason for wholly discountenancing the practice. These considerations for some time induced me to abstain from the experiment. I had seen cases in which inoculation was followed by perforating ulcer of the cornea; but, at the same time, I had seen others in which considerable clearing of previously opaque corneæ took place without any ulceration whatever.

The first case in which I tried inoculation was one which seemed peculiarly suitable for it. The patient, a discharged soldier, was in good general health, but quite helpless in consequence of the state of his corneæ. They were so hazy that the position of his pupils could not be traced, and were traversed in every direction by vessels. He had perception of reflected light and colours, but could not distinguish a hand from a sheet of paper, except by the difference of tint. Although the granular state of the lids had been nearly subdued, the condition of the corneæ during three years had been proof against every mode of treatment.

Some pus from the eye of a patient with purulent ophthalmia was applied to each conjunctiva. Intense inflammation set in, and on the third day there was already chemosis with thick purulent discharge. A week later both corneæ were so covered with a yellowish flocculent layer as to appear to be in a state of complete slough. This substance, however, in the course of a few days, had disappeared, and the corneæ were found to be entire, presenting a somewhat translucent aspect, although the chemosis and discharge still continued. As no local application except cold water was permitted, and no astringent used to control the discharge, it continued in a slight degree for some months. Meantime the corneæ, as they became clearer, presented but few traces of the vessels by which they had been so plentifully traversed. Six months after inoculation the patient could recognise features at a distance of twelve feet, and with perfect security could go about the streets of London alone. There still remained such a degree of haziness about the centre of each cornea as prevented him from reading ordinary type, No. 16 of Jaeger's specimens being the smallest characters he could readily make out.

I have since used inoculation repeatedly, and so many cases have been reported by others, that I should not have quoted this single case, except on account of its bearing upon a point which I think has not been sufficiently attended to, namely, the varying results of inoculation in respect of its inducing corneal ulceration.

The vitality of the cornea is put to a very severe test when the suppurative inflammation sets in with such intensity as is exemplified in the case just mentioned. If the cornea be abundantly supplied with blood by vessels traversing it in every

direction, it will probably resist both ulceration and sloughing; whereas, a simple opaque and non-vascular cornea may be destroyed, or at least perforated, on account of mere deficiency of blood-supply. Inoculation should therefore never be practised, unless the entire cornea is pervaded with blood-vessels. The abundant vessels which had prevented the cornea duly performing its function of transmitting light, serve to keep it alive while the inflammatory stage is going on, and so enable it eventually to recover its transparency and usefulness. The very circumstance, therefore, of the cornea being in a hyperæmic condition is favourable, as regards its ability to support the violent means employed for the restoration of its transparency.

Those who for the first time resort to inoculation in a case of corneal opacity, resulting from bygone purulent ophthalmia, will probably be dismayed when they witness the immediate result of their experiment; and will give up the cornea for lost when they see it overlapped and nearly hidden by chemosis, and catch a glimpse of its dead-yellow, slough-like surface. This, however, becomes detached, and leaves beneath it a translucent cornea, which, provided it has been well nourished with blood, may gradually advance in clearness, until it almost loses the marks of its former degeneration.

Throughout the treatment no attempt is to be made to arrest the discharge, cold water only being used as an external application in cleansing the eye. The patient should be allowed a nutritious diet, and on no account undergo depletion.

Even under the most favourable conditions, as regards the patient's general health, and the blood-supply of the cornea, inoculation must be a hazardous experiment; and it should, therefore, be reserved for those cases where the vascular opacity of the cornea has bidden defiance to all other forms of treatment, and has deprived the patient of all useful sight.

PURULENT OPHTHALMIA OF INFANTS.

(*Ophthalmia neonatorum*.)

This disease is closely allied in its symptoms to that just treated of, although not arising from the same specific form of infection.

Both diseases derive all their importance from the liability of the cornea to become ulcerated. The cause of *ophthalmia neonatorum* has given rise to much controversy; some regarding it as only an aggravated form of catarrhal ophthalmia, while others consider it as in every case due to contamination with the vaginal discharge of the mother. The latter is perhaps the more probable explanation, the difference in the intensity of the disease depending upon the more or less virulent nature of the discharge.

The ophthalmia begins a few days after birth. It may not for some time assume any intensity, and hence it is often overlooked in its early stage; and we are told that it did not begin till the child was two or three weeks old. When the child is jaundiced, the discharge assumes a deep yellow colour.

The surgeon's first object should be to ascertain to what extent the corneas are involved. Having secured the infant's head, he should carefully introduce between the lids a wire speculum, of a size and strength of spring proportioned to the small palpebral opening of so young a child. With a bit of moistened lint the discharge should be gently wiped away, so that the surface of the cornea may be thoroughly explored. If an ulcer exists, it will most commonly be found at the centre. It may occupy the whole area of the pupil, or involve all the cornea except its extreme edge, or the iris may be seen protruding through a complete perforation of the cornea in the form of a brownish nodule. If the whole cornea be destroyed, the iris will be seen bulging forward, covered by a thin glaze of semi-transparent inflammatory deposit. Sometimes it seems as if the posterior elastic lamina had resisted the ulcerative process, and still formed a thin coating to the bulging mass of iris. These are the cases which eventually exhibit *staphyloma*; the deposit upon the iris becoming by degrees thicker and denser, and assuming very much the appearance of

opaque, or partially opaque, corneal tissue, over the surface of which, at a later period, arborescent vessels ramify. When the perforating ulcer of the cornea is very large, it not uncommonly happens that the lens escapes through the aperture.

When the purulent ophthalmia is at its height, the lids are red and swollen; but when the cornea has given way, the bright rosy tint of the lids usually gives place to a dull livid colour, the swelling subsides, and the skin becomes flabby. The palpebral conjunctiva, when cleansed from the discharge, appears brightened and villous.

Treatment.—The nutrition of an infant attacked with purulent ophthalmia is so important—as the means whereby the ulcerative process may be averted, or, if that process have already commenced, reparative material may be supplied for filling up the breach—that, before alluding to local treatment, I would insist upon the importance of the child being suckled, and not brought up by hand. A weakly infant, attacked with severe ulceration of the cornea, and fed with artificial food, has hardly a chance of recovery. Of course the condition of the bowels must be attended to; but care must be taken not to lower the child by unnecessary doses of ‘grey powder’—that panacea for infantile complaints, according to popular belief. Weakly children are often benefited by a few drops—four or five—of Battley’s liquor cinchonæ, given in a tea-spoonful of milk twice a day.

In the local treatment, all depressing and so-called ‘antiphlogistic’ measures are to be carefully avoided. Blistering is perfectly ineffectual towards controlling the discharge, and only weakens and irritates the general system. Abstraction of blood by leeches is even worse, as depriving the child of that reparative material which is so urgently required for averting or healing ulceration. I know of no application better than a solution of alum, three-five grains to the ounce of distilled water—which should be injected between the lids every half-hour. It is well to inject a little warm water before using the alum-lotion, so as to wash away the discharge, and thus allow the alum to come completely into contact with the inflamed conjunctiva.

As the discharge abates, the lotion may be injected less frequently—every hour, or every two hours. Care must be taken not to chill the infant by wetting its clothes during the injecting.

The condition of the cornea must be carefully inspected from day to day. If there be a large ulcer, and the reparative process have set in, the surgeon must not be uneasy on observing that the surrounding portion of the cornea looks cloudy and reddish. This pink tinge is owing to the presence of blood-vessels, advancing towards the ulcer, and conveying to it reparative material. When the ulcer has become completely filled up, these blood-vessels will gradually disappear, and the peripheral portion of the cornea, in which they ramified, will resume its transparency.

Sometimes it is useful to change the local application, and to use a solution of nitrate of silver—two grains to the ounce—dropping a small quantity on the conjunctiva twice or thrice a day. This change of stimulus often acts beneficially, when the puriform discharge has almost ceased, and the ulcer still shows little disposition to heal. As soon as the ulcer begins to fill up rapidly, the alum or nitrate of silver should be used less frequently.

In severe cases of purulent ophthalmia, eversion of the swollen conjunctiva of the lids frequently occurs. This always gives rise to alarm among those who have charge of the child, and is often a cause of anxiety to the surgeon. It is a matter of no real importance; the eversion cannot easily be controlled by any artificial means, and is sure to cease as soon as the puriform discharge has abated.

DIPHTHERITIC OPHTHALMIA.

This very destructive affection is fortunately very rarely seen in this country, so rarely indeed, that during an experience of more than twenty years at the largest ophthalmic hospital in the metropolis, the writer has not seen in all half a dozen cases. On the Continent, and particularly in Berlin, it is reported to be not uncommon, and to

sometimes occur epidemically. It is believed to be very infectious. In some cases it engrafts itself upon what at the onset appears to be an ordinary purulent ophthalmia; in others the diphtheritic characters are evident from the outset. The eyelids soon become very swollen and hard, which makes it difficult, if not impossible, to evert them. This brawny hardness contrasts with the soft oedematous swelling of the eyelids which attends an ordinary purulent ophthalmia. There is a similarly firm chemosis of the conjunctiva, which is not intensely red as in a common ophthalmia, but has a pale yellowish tint. Eminently characteristic is the occurrence of membranous exudation on the surface of the conjunctiva. The discharge is copious, and thin, and not distinctly puriform, as in common purulent ophthalmia. The cornea becomes opaque, softened, and is destroyed by ulceration and sloughing. Recession of the diphtheritic condition is marked by softening of the brawny firmness of the eyelids and of the chemosis, increasing redness of the conjunctiva, and by the discharge assuming a puriform character. In the early stage caustics and strong astringent solutions are said to be injurious; their use is to be restricted to the late stage, when the symptoms have come to resemble those of a common purulent ophthalmia. A solution of quina sulphate, recommended by Mr. Tweedy as a topical application, has lately been very favourably reported on by Mr. Adams.

In an early stage, when the more distinctly inflammatory symptoms are very acute, local depletion by the very free use of leeches, and rapid mercurialisation with calomel in doses of gr. i. every two hours, or by inunction, are advocated by continental authorities. The results of this treatment are not very encouraging. Persons in broken or feeble health seem more liable than those in sound health to this disorder, and such persons ill bear loss of blood and mercurialisation. The continuous application of cold, preferably ice, gives ease and seems to influence favourably the course of the process. It should be replaced by warm applications if the cornea is seriously compromised.

CHRONIC OPHTHALMIA.

The acute stage of common catarrhal ophthalmia, if neglected, is apt to subside into a chronic form, characterised by a congested state of the palpebral conjunctiva, with an increase in its mucous secretion, an unnatural fulness of the caruncle and semilunar fold, and some degree of redness along the tarsal edges. The patient complains of a sensation like that produced by a small foreign body beneath the lids; luminous bodies appear surrounded by a halo of prismatic colours; the eyes water when exposed to bright light or cold winds; and the lids are gummed together in the morning.

The surgeon, on first seeing such a case, should most carefully explore the edges of the tarsi, to see if any fine eyelashes are growing irregularly, so as to touch and irritate the globe. A single delicate hair, so fine as almost to elude observation, will sometimes suffice to keep up, or even of itself to produce, most of the symptoms I have just described.

Chronic ophthalmia, characterised by the above symptoms, is not always a sequela of acute inflammation. Indeed, it more commonly occurs as a primary disease, in persons whose occupations oblige them to sit for many hours in close and over-heated rooms, while engaged on minute objects, especially under artificial light.

Treatment.—When we consider the various classes of persons liable to chronic ophthalmia, it is obviously impossible to lay down rules of treatment which shall be universally applicable. To rectify whatever may be found amiss in the general health, is the first indication. The injurious effects of artificial light chiefly depend upon the abundance of ~~the~~ rays inseparable from every form of it. These may be modified by adapting to the flame of the lamp, or gas-burner, a chimney or shade of transparent glass slightly tinted with blue. The colour should be so faint as only just to whiten the flame, without imparting to it any decidedly blue tinge.

An immense variety of substances has been used in lotions and drops for the cure of this troublesome affection. Acetate of lead, alum, sulphate of zinc, nitrate of

silver, sulphate of copper, tannin, &c., have all found their special admirers. Vinum opii was long a favourite form of drop; while the more homely washes of diluted brandy or vinegar have found favour as domestic remedies. Whatever form may be preferred, care should be taken not to make the solution too strong, and not to use it for too long a time without intermission. The object should be to stimulate the conjunctiva, for a short period, and then to give it time to resume its natural functions. Many persons, by the habitual use of strong lotions, keep up the very condition they are seeking to cure. Acetate of lead, or alum, in the proportion of from two to four grains in the ounce of water, are perhaps as useful as any of the more common substances. Bathing the eyes in cold water night and morning is in many cases preferable to the use of any medicated lotions. An occasional small blister to the temple is useful when the eyes become suddenly irritable and intolerant of light.

XEROPHTHALMOS.

This affection, which is usually the result of a prolonged subacute ophthalmia, seldom of a single acute attack, is characterised by a cuticular state of the conjunctiva. This loses the moist soft extensile character of a mucous membrane and becomes dry, opaque and scaly. The conjunctival layer of the cornea being implicated, sight is correspondingly blunted, and may diminish to loss of perception of objects. Often the loose conjunctival folds between the eyelids and eyeballs shrink and small bridges pass from lids to globe.

Moistening the opaque cornea with oil or glycerine temporarily lessens the opacity, but the improvement is of short duration. Closure of the eyelids by uniting their free edges for several weeks has also been tried, but the result of this, as indeed of all other treatment, is not encouraging.

INJURIES OF THE CONJUNCTIVA.

The more serious of these are due to contact with escharotics, heated fluids, or melted metal. Slight lacerations or cuts of the conjunctiva, not involving the sclerotic, require only very simple treatment—water-dressing and closure of the lids. Strong mineral acids, caustic alkalies, and other chemical substances, often produce the most destructive effects upon the conjunctiva and cornea, causing bands of adhesion to form between the lids and the globe, and inflicting upon the cornea such an amount of opacity as wholly to destroy sight. The damage in these cases is so instantaneous that the surgeon has hardly ever the opportunity of neutralising the destructive fluid. If at hand at the moment of the accident he would of course at once inject between the lids such a fluid as would chemically decompose the acid or caustic alkali, and form a neutral salt. Afterwards a little castor-oil or olive-oil may be dropped upon the surface of the globe, and water-dressing applied over the closed lids.

Where melted metal has spurted into the eye, the surgeon should always evert the upper lid, and explore all the folds of the conjunctiva; for large portions of metal will sometimes lodge beneath the lids in the most singular manner, and remain there quite unsuspected for a long time.

When lime, mortar, sand, or other solid matters, have been thrown against the eye, the upper lid must be everted, and every particle of grit removed in the most careful manner with a small scoop. In such cases it will not do to trust to injections of water only, although they may be useful after the scoop has done its work. The continuous application of ice to the eyelids is of very great service in reducing the intense inflammation which quickly follows such injuries.

If the surface of the conjunctiva presents an opaque thickened appearance, as if it had been boiled, and the cornea is also of an opaque and pearly hue, the damage to sight is irreparable, and only slight improvement is to be hoped for. In such cases the surgeon must take care not to weaken the patient by bleeding or low diet, for

it is by keeping up the patient's reparative power that the life of the corneal tissue is to be sustained, and sloughing averted. Where a portion of the cornea is densely white and opaque, and the rest only slightly cloudy, the latter part may recover much of its natural transparency.

In those cases where the opposed surfaces of the palpebral and ocular conjunctiva have sloughed, it is impossible to prevent the formation of bands of adhesion; but these may be somewhat limited by the frequent use of a probe, to break down the newly-formed granulations, only wearing a glass shield whilst cicatrization is progressing.

AFFECTIONS OF THE SUBCONJUNCTIVAL TISSUE.

CEDEMA.

Pressure upon the trunk of the ophthalmic vein or its branches, by obstructing the return of blood from the conjunctiva and subjacent areolar tissue, is liable to produce œdema. In slight cases the œdema is confined to the lower part of the globe, where the distended conjunctiva sometimes overhangs the edge of the lower tarsus: it is only in extreme cases that the œdema extends to the upper part of the globe. In old persons, whose tissues are very lax, I have seen the margin of the cornea overlapped by the œdematous conjunctiva.

Edema and chemosis differ in degree and kind; the former being a mere exudation of serum in consequence of pressure on the veins leading from the part, while the latter term is restricted to those cases where the conjunctiva and subjacent areolar tissue are actively inflamed. Abscess in the lids or in the lacrymal sac, tumours, and exostoses in the orbit, periosteal thickening in the neighbourhood of the ophthalmic vein—in short, any direct pressure on this vessel, may give rise to œdema, which cannot therefore be regarded as of itself constituting a disease, or as demanding attention, except as a symptom of something more important which has given rise to it.

ECCHYMOSIS.

Some of the small vessels beneath the conjunctiva may give way in consequence of a violent effort, such as coughing or vomiting, or sometimes without any assignable cause; in children with whooping cough such extravasation often takes place to a great extent. The blood may appear as a small patch on the white of the eye, or it may quite hide the sclerotic, and extend up to the edge of the cornea. The appearance is so peculiar that it can never be mistaken for inflammatory injection. In the latter the individual vessels can always be distinguished, while the extravasation presents the uniform aspect of a thinly spread-out clot.

Subconjunctival ecchymosis not uncommonly causes great alarm to the patient; but, except for its unsightliness, it is quite unimportant. The scraped root of the black bryony (*Tamus communis*) made into a poultice with bread crumbs or linseed meal, applied over the closed lids, and renewed every six hours, will hasten the absorption of blood; or the closed lids may be covered with a compress wetted with Liq. plumbi subacet. in the proportion of ʒiv to ʒi of distilled water. If this cannot be worn, frequent sluicing with cold water is the best thing to be done. Nothing, however, will cause the blood to be absorbed until after the lapse of several days.

PINGUECULA.

After the middle period of life, especially in persons who have been much exposed to the weather, or have lived in hot climates, it is very common to see small yellowish elevations on the sclerotic, close to the edge of the cornea, and on the equator of the eyeball. They are sometimes surrounded and traversed by a few fine vessels. When these little elevations attain their full size, they will be observed to have a somewhat triangular form, the base corresponding to the cornea. They have received the name of *pinguecula* from their being supposed to consist of fat; much of their bulk, however, is made up of fibrous tissue. Pingueculæ are growths

so entirely harmless that they would not call for a remark, were it not that they very often give rise to the most serious alarm in the patient, who believes that they will gradually grow over the pupil and obstruct the sight. An explanation of their real nature comprises all that is required on the part of the surgeon.

PTERYGIUM.

This consists in a reddish, fleshy-looking growth extending from the semilunar fold to the cornea, the margin of which it frequently oversteps. It has a triangular shape, its base corresponding to the inner or outer canthus. Occasionally pterygium is present at both sides, and exceptionally they are met with in other situations than the horizontal equator. Slighter forms of this growth are met with, in which, instead of looking like a portion of muscle, the fibres are so thin and delicate as rather to resemble an aponeurosis with a few muscular fibres intermixed. No muscle, however, is found in these growths, which consist of fibrous tissue abundantly intermixed with blood-vessels.

Pterygium, like pinguecula, is found in persons past the middle period of life, and especially among sailors and those who have lived in tropical countries. The dust and glare which are there so abundant, may probably be an exciting cause. A very well-marked case came under my care in a mason and plasterer, who, although always residing in the neighbourhood of London, had of course been much exposed to dust of various kinds. The largest pterygium I ever saw, however, was in a countryman from Essex, in whom the apex of the growth, instead of stopping short of the area of the pupil, as is commonly the case, spread so far across the cornea as almost to hide the whole of the pupil. In this case I removed the growth; and whenever the apex extends so far as to occupy a large portion of the cornea, the deformity it produces may demand an operation. The lids being held asunder with a spring speculum, the lax portion covering the sclerotic is to be nipped up in a forceps, and cut across with a fine scalpel midway between the edge of the cornea and the semilunar fold. The portion extending towards the cornea may then be dissected off the sclerotic, great care being taken when that part is removed which adheres to the cornea. It is well not to remove the inner third of the pterygium, as otherwise the semilunar fold and caruncle are apt to retract, which afterwards gives an unpleasant prominence to the eyeball. The tendency to recurrence is sometimes strongly marked. On this account some have advocated the transplantation of the apex of the pterygium in an upward or downward direction, where, should it continue to grow, it will not encroach upon the cornea and will be hidden by the eyelids.

No other local treatment than removal with the knife or scissors is of any avail in getting rid of a pterygium. Stimulating lotions and drops only excite it to grow; and the varieties of pterygium described by authors, under the names of *sarcomatous*, *fungous*, *cancerous*, and *malignant*, were probably nothing more than common forms of the growth, irritated and teased by escharotics.

FATTY TUMOURS.

Fatty deposits to any large extent beneath the conjunctiva are uncommon. The few cases I have seen occurred in children, and the tumours all occupied the same position, namely, the line of reflection of the conjunctiva from the lower lid on to the globe. They extended from near the lower edge of the cornea to the outer canthus, were of an elongated form, almost resembling a haricot bean, and were partly concealed by the lower lid. On dividing the conjunctiva and the proper fibrous envelope, the fatty mass was easily turned out.

Fibro-cellular. (Dermoid tumours, not cysts).—The lipomata just described differ from those so frequently met with in the subcutaneous tissue of the trunk and limbs in the relatively large amount of fibro-nucleated tissue they contain. Of much less infrequent occurrence than these are little tumours composed almost wholly of a fibro-cellular tissue. They are usually seated near the anterior border of the

sclerotic, or jointly on this and on the cornea. In size they seldom greatly exceed a split pea. Their surface is cuticular, and not infrequently a few fine hairs grow from the summit of the tumour. They are always congenital.

They should be dissected off the surface of the eyeball, care being taken not to carry the knife too deeply into the cornea.

Polypi.—Small, innocent, pedunculated tumours of the conjunctiva are occasionally observed. They almost invariably spring from the palpebral conjunctiva and usually near the sinus. I have only seen them in relation with the lower eyelids. They should be snipped off.

Cancer.—Primary cancer of the conjunctiva is very rare. The few instances which have come under my notice were epitheliomatous; they occurred on the ocular conjunctiva and had a distinctly papillose, warty character. Thorough excision and cauterisation of the wound with nitrate of silver in two instances procured a long immunity from return; in another case recurrence necessitated excision of the eyeball.

CYSTICERCUS TELÆ CELLULOSE.

This parasite is occasionally found in the subconjunctival cellular tissue, but it appears to be of very rare occurrence. I have seen but two instances, both in females, one patient being six, the other eighteen, years old. The appearance was that of a rounded body, about as large as a pea, midway between the inner canthus and the cornea. There was a good deal of vascularity in the conjunctiva covering and surrounding it. In the first case a little watery bladder, rather larger than a pin's head, had been observed about eighteen months before the patient was brought to me. In the second case, no account could be given as to the first appearance of the growth. On the conjunctiva being divided, the cysticercus slipped out, and was at once recognised under the microscope. Sichel, in his *Iconographie*, gives a very good figure of a cysticercus in the position I have described (pl. lxxii. fig. 2), and also of one developed beneath the plica semilunaris (fig. 1). In other figures of the same plate, the animal is shown both in its natural size and magnified.¹

At the time I saw these two cases the connection between the development of tænia in the intestines, and of cysticercus in other parts of the body, had not been pointed out; nor was it suspected that two creatures so dissimilar were really the same animal under different forms of development.²

STAINS FROM NITRATE OF SILVER.

Before quitting the subject of affections of the conjunctiva and subjacent tissue, I may say a few words respecting the serious disfigurement which results from the prolonged use of nitrate of silver in solution. No surgeon who understands the real action of this substance—its invaluable efficacy in catarrhal ophthalmia, and its inutility or injurious effects in affections of the cornea—would be likely to employ it in such a manner as to produce permanent staining of the tissues of the eye; for in no case is its prolonged use of any service; the good it does, it does in a few days. Patients, however, have such unbounded faith in the efficacy of eye-drops and eye-waters, that they will frequently continue the use of them for months and even years.

One of the worst cases of staining with nitrate of silver I ever saw was the following. A woman, with incurable opacity at the centre of the cornea—the cicatrix of an ulcer, in fact—had been ordered to use drops of nitrate of silver. This she did for some months, under a surgeon's advice. She then went to another part of the country, but still continued the use of the drops, putting in, as she assured me, 'two drops every day for ten years.' The whole of her sclerotic was of a dirty sepia tint, most marked towards the lower part of the

¹ Gräfe mentions five cases of subconjunctival cysticercus as having occurred in his *clinique* during a period of thirteen years. *Archiv für Ophthalmologie*, xii. 2, 174.

² See Küchenmeister, *On Animal and Vegetable Parasites of the Human Body*; and Von Siebold, *On Tape and Cystic Worms*; published by the Sydenham Society, 1857. See also the essay on PARASITES in the Appendix.

globe. The cornea itself slightly partook of the same tint, and the conjunctiva of the lower lid, thickened and vascular, looked as if a brush dipped in liquid sepia had been passed over it, the dull red colour of the conjunctiva being only seen where the membrane had formed a fold.

In another case, where this discoloration existed in a less marked degree than in the case just mentioned, I tried the effect of a solution of cyanide of potassium. The patient was an intelligent man, and could thoroughly understand the principle of the treatment, which was to keep the whole surface of stained tissue for a lengthened period in contact with the fluid. This was effected by the help of an 'eye-glass,' and I told the patient to draw down the lower lid, and to fix it against the cheek-bone with the rim of the glass, before throwing his head back. After several months but little benefit had resulted, and I then tried a solution of hyposulphite of soda, beginning with a strength of ten grains to the ounce of water—as the effect of the substance was unknown to me—and gradually increasing it up to a drachm to the ounce. The change effected was very slow, but when I last saw the patient the stain was barely traceable on close inspection.

CHAPTER IV.

DISEASES OF THE CORNEA.

THOROUGHLY to appreciate the slight changes in the cornea which are capable of affecting the sight, the surgeon should clearly understand that the normal condition of the part consists in absolute transparency of its whole thickness, and perfect polish of its surface; every deviation from these conditions is an evidence of some morbid action.

When a healthy eye is examined near a window, the image of the window-frame ought to be depicted on the surface of the cornea with the most perfect sharpness and clearness of detail. A slight amount of inflammation, just enough to cause some thickening of the epithelium, destroys the brilliant polish, and causes the image of the window to appear blurred and dull, and the lines of the sash-bars crooked and wavy. This appearance is often important as giving notice that inflammation of other tissues of the eye may be going on: as in the early stage of Glaucoma, where this dull condition of the epithelium is always to be seen.

CONICAL CORNEA.

(*Staphyloma corneæ pellucidum*; *Keratoconus*.)

This curious and rare¹ malformation consists in a change in the form of the cornea from a segment of a sphere to a cone, the transparency of the part remaining unaltered. It is met with in both sexes, in women much more frequently than in men. It is almost unknown in childhood; it usually begins late in youth, or in young adult life, and its subjects are generally delicate.

The aspect of a patient with conical cornea in a high degree is so peculiar that, when once seen, the affection can never afterwards be overlooked. The eye, viewed in front, has a brilliant and sparkling appearance, as if a tear were hanging just in front of the pupil. When seen in profile, the conical shape of the cornea is at once recognised. The position of the iris is unchanged, and its movements are perfectly natural; nor is any other tissue, except the cornea, observed to be affected. In saying that a conical cornea is perfectly transparent, I should modify the remark as far as concerns the extreme apex of the cone, which sometimes, when viewed closely, presents an appearance of slight opacity. In some cases this seems due to an actual

¹ That the disease is very rare may be seen by reference to a table which I contributed to the *London Journal of Medicine* (vol. ii. 1850), showing the number of cases of conical cornea occurring among the patients annually received at the Moorfields Hospital from 1819 to 1849.

haziness in the tissue itself; but the appearance is frequently caused by mere refraction of the rays of light. There seems no good reason for attributing this slight cloudiness of the apex of the cone to the friction of the lids.

The apex of the cone usually corresponds to the centre of the cornea; but not infrequently in slight cases it has been observed to deviate from this position. When obliquely illuminated with a collecting lens, or with the ophthalmoscopic mirror, the side of the cone on which the light falls gives a brilliant reflex, which contrasts strongly with the dark opposite side of the cone. In both methods of ophthalmoscopic examination, the images of the retinal vessels appear greatly disturbed, slight movements of the eye or of the examiner impart to such images an illusory circular motion around the base of the cone. Short-sightedness is often the first noticed symptom, but, as the change goes on, a remarkable refraction of the rays of light is produced; the flame of a candle appears surrounded with a halo, then it seems to be divided into a multitude of diverging rays, and sometimes, instead of a single flame, several flames are seen, arranged in a circle; the myopia is complicated with very irregular astigmatism. When the last stage of conical deformity has been reached, the patient cannot read, even at the shortest focus.

In the few cases in which conical corneæ have been dissected, the apex of the cone has been found very much thinned.¹ The mode in which the disease originates is at present quite unexplained; and in proportion to the obscurity which attends its cause have arisen the most varied suggestions for its treatment. Repeated evacuations of the aqueous humour, the same operation followed by pressure on the cornea, removal of the lens by extraction or solution, these, and perhaps other forms of operation, were formerly tried, but without benefit.

Tyrrrell tried the effect of displacing the pupil towards the corneal margin. With the blunt hook he invented, he drew out a small piece of the iris, and cut it off, leaving a portion of the cut tissue entangled in the wound. His object was to bring the pupil opposite the flatter portion of the cone; but the result did not answer his expectations. A better form of this operation has been lately devised, whereby the pupil is transformed into a long narrow chink, reaching quite across the cornea. A small wound is made close to the corneal margin, a blunt hook or fine forceps is introduced, and the pupillary portion of the iris, having been drawn out, is tied with a fine ligature, *Iridodesis*. At a later period, when the corneal wound is healed, and the aqueous humour retained, a similar operation is performed on the opposite side of the cornea. This operation should, I think, be limited to those extreme cases of conical deformity which cannot be palliated by an optical contrivance.

The occasional occurrence of iritis after iridodesis has very generally led ophthalmic surgeons to abandon it, and where an operation on the iris is deemed advisable, to practise, instead of iridodesis, a very narrow iridectomy. The excision of a very narrow segment of the iris is sometimes followed by considerable improvement of sight. Free excision of a large segment of the iris, invaluable for the relief of undue tension of the eyeball in glaucoma, has been tried in conical cornea, with the hope that the conicity might lessen after it; but this has not been realised, and the great dispersion entailed by the very large pupil not being counterbalanced by recession of the cornea, this operation has been relinquished. Von Gräfe, observing the contraction which follows cicatrisation, shaved off the apex of the cone, taking care not to remove the whole thickness of the cornea, and cauterised the wound with nitrate of silver, which prevented too rapid healing. The flattening of the cone thus produced effected in some instances not inconsiderable visual improvement. The details of this operation were improved by Mr. Bowman, who removed the apex of the cone with a minute trephine. The disfigurement by the opaque white scar may be lessened by subsequently tattooing it, which also has the advantage of rendering the scar more impervious to light, and thus lessening the confusion produced by dispersion.

The depletory measures formerly practised are not only useless, but positively

¹ *Royal London Ophthalmic Hospital Reports*, vol. ii. p. 155.

hurtful. An attempt should be made to improve the health by fresh air, sufficient and suitable food and tonics; all strain of the eyes should be avoided.

Slight cases are sometimes benefited by spherical concave glasses, alone or in combination with a cylinder; but in the complete stage of the disease, the sight is little, if at all, aided by glasses of any kind. A small aperture, like a pin-hole, in a metallic plate, held close to the eye, will in most cases of confirmed conical deformity enable a patient to read at a distance of five or six inches who previously had been unable to discern a letter. If, instead of a hole, a slit about three-quarters of an inch long and the thirtieth of an inch wide be made in a metallic plate fixed into a spectacle-frame, a considerable extent of lateral vision is obtained, without any necessity for moving the head in the way which is necessary when objects are viewed merely through a small circular aperture. It was the benefit derived from this slit in a metallic diaphragm which suggested the operation of iridodesis just described.

ARCUS SENILIS.

This term is by no means well chosen, for the change in the cornea which it implies commences long before old age can be said to have arrived, and by the time the patient has reached the age of sixty or seventy, the arc has usually been converted into a complete circle. Canton described the appearance as being due to a fatty degeneration of the peripheral portion of the cornea; and the term 'arcus adiposus' would therefore be well applied to its early stage, and 'annulus adiposus' to that condition in which the white ring completely encircles the cornea. In many persons past forty years of age, in some even at a much earlier period, an opaque whitish crescent may be observed skirting the margin of the cornea, either at its upper or lower part. This opaque crescent is the commencement of the so called 'arcus senilis'; and on close inspection it will be seen that the opacity is not an extension of the white tissue of the sclerotic into that of the cornea, but that a narrow interval of partially clear cornea always intervenes between the two opaque structures. In some old persons, the circle assumes a chalky whiteness, and presents a very striking appearance.

'Arcus senilis' is considered by some observers to indicate the co-existence of fatty degeneration of the heart. As far as the eye itself is concerned, the change can be considered as of very little importance. It certainly does not, as has been asserted, in any way contra-indicate the operation of cataract by extraction; for I have many times carried my section through a strongly-marked 'arcus senilis,' and the wound has become quickly and firmly united.

INFLAMMATION OF THE CORNEA.

(*Keratitis; Corneitis.*)

The healthy cornea, as I have already observed, is of the most perfect transparency, and its surface smooth and brilliant in the highest degree. These qualities are lost as soon as the part becomes inflamed; a general haziness overspreads the whole structure, and the surface looks like a steamy glass.

If the inflammation be acute, a crescentic plexus of vessels will be seen passing from the edge of the cornea for some little distance—a line or more—into its substance. These vessels are so fine, and so closely set together, that they produce the appearance of a small patch of blood smeared upon the surface of the cornea. With a lens of an inch focus, the individual vessels composing the plexus may be identified. This characteristic plexus sometimes involves a third or even a half of the corneal circumference.

A zone of pink vessels is always seen in the sclerotic adjacent to the cornea, whenever any form of active keratitis is present; this *sclerotic zone* also exists whenever the iris is inflamed. It is therefore always to be regarded as an important sign. As acute keratitis advances, some portion of the hazy cornea may become more

decidedly opaque, and of a pale yellow tint; this shows that softening is going on, which may lead to actual giving way of the part. Intolerance of light and abundant secretion of tears accompany keratitis. The larger venous trunks of the conjunctiva become full and distended, but there is an absence of that fine vascular network in the conjunctiva which characterises ophthalmia.

One eye is usually attacked at a time, but the other may sooner or later become involved, and it very often happens that the second eye becomes inflamed just as the first is recovering.

Children and young persons are the most frequent subjects of keratitis, and the disease is rare after the age of twenty. The subjects of it are usually of a weakly, irritable constitution, often pale and anæmic; in some cases presenting the swollen cervical glands and other marks of scrofula.

The prognosis is favourable in proportion as the patient is young, and is seen at an early stage of the disease.

The mischievous and too common practice of keeping such patients confined to darkened rooms often induces a morbid irritability of the nervous system, and an intolerance of light, which is still further aggravated by the irritating drops so unsparingly applied to eyes affected with corneal inflammation.

Under judicious management a case of keratitis occurring in a child may sometimes pass off without leaving a trace of opacity. But when the disease occurs after puberty, and is severe and obstinate, perfect transparency is hardly ever restored, and the cornea remains ever afterwards rather more convex than natural, and very faintly mottled with opacities and partially transparent interstices. These opacities resulting from long-continued keratitis, without ulceration, require to be thoroughly understood; for the surgeon who has not made himself familiar with their appearance will be sure to overrate the patient's powers of sight. It seems as if long-continued keratitis in patients who have passed childhood were attended with some peculiar change in the structure of the cornea, whereby those portions which present only the slightest traces of opacity become, from irregular refraction of the rays of light, unable to transmit a clear and well-defined image of objects.

Treatment.—I have already alluded to the constitutional peculiarities commonly met with in patients who are the subjects of keratitis. They are in every way unfitted to endure the 'antiphlogistic' measures recommended in so many works on eye-diseases. The diet should be nutritious and abundant, but not given in such quantities as to oppress the stomach and impair digestion. Very young children are almost always better without beer or wine. The former should be given to older children once a day if they have been accustomed to it; but wine can only be required by children suffering from extreme debility; in ordinary cases it hurries the circulation, and increases the general irritability of the nervous system. Of course the condition of the bowels is to be carefully attended to; and where the state of the biliary and other secretions may demand the use of mercury, an occasional dose of calomel—one or two grains, with or without a proportionate quantity of rhubarb—is to be given; but anything like a mercurial course is to be avoided. Iron is, of all substances, the most beneficial in cases of genuine keratitis, but it frequently fails in consequence of being given in too large doses, and for too long a time without any pause. The tinctura ferri sesquichloridi is the form I usually prefer, giving it invariably directly after food, or even during a meal, and in doses varying, according to age, from five to twelve drops twice a day. The syrupus ferri iodidi is sometimes useful. Occasionally, when the patient is feeble, ill-nourished, or of phthisical tendency, cod-liver oil may be given as well as the iron, or even, for a time, instead of it.

Counter-irritation, by means of small blisters to the temples, is often valuable in combating the intolerance of light; and tincture of iodine, applied to the skin of the lids, also conduces to the same end, and is preferable to blisters in patients of extreme delicacy of constitution.

Inflammation of the cornea is essentially a tedious disease, and the surgeon must often wait patiently for weeks, and even months, before the transparency of the part is restored. Hence it will be seen how necessary it is to give the tonic medicines in

small doses, such as the patient can go on with for a considerable period, instead of attempting to conquer the disease at once by giving large doses, which cannot be persevered in without derangement of the stomach and liver.

Warm fomentations, night and morning, or steaming the eyes over hot water, will usually be found to allay their irritability; but all stimulating lotions and drops do harm.

How any one who has seen much ophthalmic practice can recommend the application of solid nitrate of silver to the conjunctiva in cases of keratitis, I cannot comprehend. The same substance in solution, and the sulphates of copper and zinc, are also frequently employed, and sometimes the ointments of the nitrate and nitrico-oxide of mercury are added, as if on purpose to increase the irritation already existing.

'SCROFULOUS OR STRUMOUS KERATITIS.'

I have observed that the well known disease commonly called Scrofulous Ophthalmia (*Phlyctænular Ophthalmia* of Mackenzie) derives all its importance from the fact that the cornea is implicated; and I therefore propose to separate the disease from the group of conjunctival inflammations, to which alone the term 'Ophthalmia' strictly belongs, and to treat of it under the head of Inflammation of the Cornea.

It specially attacks children, but certainly is not always confined to those of scrofulous constitution; at least it is met with where there is no evidence of tubercular disease. The most striking symptom is extreme intolerance of light (*photophobia*), and general irritability of the eyes and of the whole system. The local affection of the cornea shows itself either in a small whitish elevation (*phlyctænula*), or an ulcer. In either case a long plexus of vessels runs from the corneal margin to the morbid spot. This long plexus or lash of vessels is quite diagnostic of the disease. It is sometimes seen when the rest of the cornea is almost clear, but more commonly there are several *phlyctænulae* or ulcers, and the whole of the cornea is more or less hazy. The intolerance of light I have mentioned, as being characteristic of the disease, causes violent spasm of the orbicularis palpebrarum, which is increased when the surgeon makes any attempt to examine the eyes. The intolerance is often much increased by the too common but most injudicious practice of keeping the patients in dark rooms. After many hours of darkness, the sudden admission of light is of course extremely painful. If the intolerance is very great, or the child too young to be open to persuasion, the examination must be made by means of the wire speculum.

The pain caused by exposure to light is often out of all proportion to the extent of corneal disease. In some extreme cases the surgeon is surprised to find merely a small whitish elevation (*phlyctænula*), or an ulcer the size of a pin's head, with the characteristic streak of vessels reaching to it from the edge of an almost clear cornea.

In true cases of this form of keratitis there is hardly any increase in the mucous secretion from the conjunctiva, but the flow of tears is profuse, and they gush out each time the lids are separated. There is a more or less marked zone of vessels in the sclerotic immediately around the cornea, but no general redness of the globe, the chief increase of vascularity being due to distension of the larger veins of the conjunctiva. The lids are often raw and excoriated at the edges, and the outer commissure is inclined to crack and bleed. Swollen and fissured lips and *alae nasi*, excoriations and cracks behind the ears, eczema on various parts of the face, and eruptions on the scalp, are occasionally found to accompany this disease of the eyes in the more severe and long-continued cases.

Treatment.—Both the skill and patience of the surgeon are often severely tried by these cases, especially if they have been neglected, or treated injudiciously, before coming into his hands. Long-continued doses of mercury, seclusion in dark rooms involving the loss of air and exercise, and too much of food and stimulants, are the

common sources of unsucess as regards general management, whilst the local application is too often just that which is most hurtful—namely, nitrate of silver

Under the head of Catarrhal Ophthalmia I have spoken of the valuable properties of this substance in solution, in cases where the inflammation is limited to the conjunctiva; and I have also mentioned how beneficially the application of the solid nitrate acts in arresting the rapid ulceration of the cornea in purulent or gonorrhoeal ophthalmia. But the too common practice of dropping-in a solution of the nitrate in cases where the cornea is attacked either with phlyctenulæ or ulcers, is most mischievous, and often prevents the cure of a case which in other respects may have been judiciously treated.

I have said that children attacked with this disease should by no means be shut up in dark rooms. Light is as essential to the health of animals as of plants, and all inconvenience from bright light can be averted by the use of a large shade, or in elder children a pair of tinted spectacles. Out of doors a blue or green veil may be added. Moderate exercise in the open air should be taken whenever the weather is mild and dry, and sea-air is generally the most desirable, provided the place selected be not too bleak and windy. I have alluded to the ill effects of too much food and stimulants; but in doing so, I would not be supposed to recommend low diet; on the contrary, there should be an abundance of nutritious, easily digested food. My remark was directed against that pernicious practice of stuffing young children with more animal food than the stomach can properly digest, and over-exciting their irritable circulation with wine and beer, as if their disease could, as it were, be taken by storm and extinguished by mere eating and drinking. Of course there are exceptional instances of very weakly children who require a small quantity of wine; but, as a rule, beer is preferable at an early age, and to those unaccustomed to stimulants pure milk will often be found of far more service.

With respect to drugs, I know of nothing so useful as iron in cases of keratitis, whether attended with phlyctenulæ or ulcers. It may be given alone, or in combination with quinine, according to circumstances. The reason why iron is so often ineffectually prescribed in this disease and in many others, appears to me to be that it is given in too large doses and at wrong times. The form I prefer is the tinctura ferri sesquichloridi, in doses of five, ten, or twelve drops, twice or thrice a day, to children ranging from five to fifteen years of age. It is best taken in water, and always immediately after a meal. Weakly children may at the same time take with advantage cod-liver oil. Every fortnight or so the iron may be discontinued for a couple of days, and if the bowels have become confined, or the liver appear to be deranged, a mild aperient may then be taken, with half a grain, a grain, or two grains of calomel, according to age and constitution.

Of local applications none are so generally employed as blisters; and no doubt, when used judiciously, they are very serviceable in subduing that intolerance of light which is one of the most distressing features of the disease. But here again a great mistake is frequently made in applying blisters of too large a size, and without sufficiently discriminating between those constitutions that will and those that will not bear them.

In feeble anæmic subjects a blister, even of small size, will often produce considerable depression; and in very young children with irritable skin, will bring out a troublesome eczematous eruption. The best effect is produced by applying blisters the size of a shilling to the temple, allowing the part to heal quickly, and repeating the blister when the cuticle is reproduced at the end of a week or ten days. A more rapid form of counter-irritation is that produced by undiluted tincture of iodine, painted on the skin of the upper lid. This may be repeated as often as the skin recovers its natural condition.

The lids may be bathed night and morning with warm water, or the steam of hot water may be allowed to play against them, which avoids the mechanical irritation of rags or sponges.

Vaseline may be smeared along the eyelashes at bedtime. Lotions of acetate of lead, or alum, two or three grains to the ounce of water, are sometimes useful where

there is on the cornea merely a small opaque patch (phlyctæna), with the characteristic lash of vessels running to it; but whenever an ulcer exists lead-lotions are improper, as the carbonate of lead, which is precipitated from them, is liable to form an insoluble white deposit in the cicatrix.

Leeches always do harm in cases of true keratitis with ulceration of the cornea.

To get rid of the plexus of vessels running from the edge of the cornea to the phlyctænula or ulcer on its surface, it has been gravely proposed that the vessels should be cut across with a lancet. This is, indeed, beginning at the wrong end. '*Ubi stimulus, ibi affluus*;' so long as an irritable patch of deposit or an ulcer exists, so long will an irregular supply of blood be sent thither. Heal the ulcer, or get rid of the irritability of the cornea, by constitutional means, and the plexus of vessels will vanish.

The opacities remaining after a long-continued attack of scrofulous ophthalmia are, to a certain extent, permanent; that is to say, if they result from the healing of ulcers. But if the ulcer be superficial and the child very young, it is surprising to see how faint a trace remains in after-life, to mark the site of the cicatrix.

PARENCHYMATOUS OR INTERSTITIAL KERATITIS.

It is to the careful observations of Hutchinson that we owe the true knowledge of this remarkable form of corneal inflammation. Not that he detected a disease which had never been seen before; on the contrary, it was in patients who might have been selected as affording typical specimens of 'strumous ophthalmia' that he first declared the morbid appearances to be due, not to scrofula, but to inherited syphilis. He named the disease 'chronic interstitial keratitis,' but I think we may fairly substitute the shorter term *syphilitic*. No confusion can arise from thus naming the disease, because there is no special form of corneal inflammation connected with acquired syphilis, the chronic interstitial form being met with exclusively as a sequela of an *inherited* taint. [I have exceptionally seen this form of keratitis follow acquired syphilis in young adults free from every evidence of antecedent inherited taint, and less infrequently in children, from whom all other grounds for suspecting inherited syphilis were absent.—J. W. H.]

The subjects of this form of keratitis are children and young persons from five to eighteen years of age, and most frequently it is an eldest child that comes under observation. The disease begins at the centre of one cornea, in the form of a diffused haziness, like that of ground glass. Very soon whitish dots appear in the midst of the haze, not on the surface, but in the very substance of the cornea. These dots generally run together, and thus increase the amount of central opacity. At first there is but little attendant vascularity of the sclerotic and conjunctiva, but as the central opacity becomes more marked, these tissues become reddened, and a fine plexus of vessels spreads on the cornea itself, and gradually pervades the opaque portion, affecting the upper and central part of the cornea in preference to its lower half. Throughout the whole course of the disease there is no tendency to ulceration.

Usually within about two months—or it may be much earlier—the other cornea begins to be affected, the disease commencing, as in the eye first attacked, by a central haziness.

The vascularity of the cornea, when the disease is at its height, is wholly unlike that which attends granular lids, and other chronic forms of keratitis. In the latter the vessels are large and superficial, whereas in the disease now under consideration they penetrate the cornea so deeply, and are so fine and closely set together, that the effect produced is that of a tissue infiltrated with blood.

'In almost all cases the subjects of this keratitis,' says Hutchinson, 'present a very peculiar physiognomy, of which the most striking signs are, a coarse flabby skin, pits and scars on the face and forehead, cicatrices of old fissures at the angles of the mouth, sunken bridge to the nose, and a set of permanent teeth peculiar for their smallness, bad colour, and vertically notched edges.' He adds: 'As diagnostic of

hereditary syphilis, various peculiarities are often presented by the other teeth, especially the canines, but the upper central incisors are the *test-teeth*. When first cut, these teeth are usually short, and the cutting edge is narrow from side to side, and very thin. After a while a crescentic portion from their edge breaks away, leaving a broad, shallow, vertical notch, which is permanent for some years, but between twenty and thirty usually becomes obliterated by the premature wearing down of the tooth.' 'I have not met with a single example of well-characterised interstitial keratitis in which the teeth were of normal size and shape.'

More extensive experience has caused Mr. Hutchinson to modify this last remark, and he mentions several exceptional cases in which all the appearances of syphilitic keratitis were present, in association with well-formed teeth.

One very remarkable instance of keratitis—I think the severest I ever saw—occurred in my own practice, in a young lady whose teeth were quite remarkable for soundness and symmetry; but in her the peculiar physiognomy was well marked, and her history completely confirmed the fact of her inherited syphilis. I have also seen some striking cases, in which patients with well-formed features, and clear and ruddy complexions, had strongly-marked syphilitic keratitis; but their teeth were more or less affected. We therefore may meet with severe syphilitic keratitis in patients with healthy physiognomy and deformed teeth; or still more rarely—in those with faultless teeth and the syphilitic cast of features; but to find the true form of keratitis in connection with both good teeth and good complexion also, is, I think, next to impossible.

I frequently notice that medical men who have not read Hutchinson's careful descriptions, but have only heard of 'notched teeth,' expect to find serrated edges, such as one so often sees in newly-cut healthy incisors. 'Serrated,' however, implies a series of notches. A single notch is that to which Hutchinson first drew attention; and the following figure, copied from his work, will at once show the reader what he is to look for.

FIG. 4.

In adults the notch often becomes worn away, but even then the tooth retains a characteristic shape. I liken it to that of a screw-driver, being wide at the base, where it joins the gum, and narrow at its cutting edge; while its lateral edges are thick and rounded. The lower incisors never lose their peculiar form, which is more or less cylindrical, and they are commonly wider apart than healthy teeth.

It must be always borne in mind that these syphilitic peculiarities in the teeth are only met with in the permanent set. The first set are not notched, but they are usually stunted and prone to premature decay.

Treatment.—A combined specific and tonic plan is advocated by Hutchinson, as being more efficacious than one exclusively tonic, and he advises the cautious use of mercurials and iodides. He prefers to administer the mercury by rubbing-in the milder ointment, always avoiding pyralism, and gives internally iodide of potassium and iodide of iron.

I believe iron, under some form or other, to be the one drug needful. It should be given in small doses, because the cure is necessarily very slow, and the medicine must therefore be continued for many months. An occasional small dose of calomel—a grain or so once a fortnight—is requisite to prevent the iron deranging the liver, but I do not think 'a mercurial course,' as it is termed, either necessary or beneficial. The forms of iron I prefer are the *tinctura ferri sesquichloridi*, and *syrup. ferri iodidi*. For a young child six or seven years of age, eight or ten drops of the tincture, given once a day immediately after a meal, will be a full dose; each fortnight it may be left off for a day or two, and a grain of calomel given. Even for

patients sixteen or eighteen years old, the dose of the tincture need never exceed fifteen or twenty drops.

Good diet, pure air, and all things calculated to improve the condition of the blood and tissues, are of the utmost importance in treating the cachectic subjects of inherited syphilis. The surgeon must ever bear in mind that the severer forms of syphilitic keratitis require a very long time for their cure. A bad case will require a year or even longer, and the friends of the patient ought at the very first to clearly understand this. A rapid cure is quite impossible. If only the vascularity of the cornea disappears, and from month to month the part becomes less opaque, the very worst case may terminate satisfactorily. It is, however, unreasonable to expect that in very severe cases absolute transparency of the cornea will ever be attained.

A very chronic kind of iritis commonly accompanies the severer forms of syphilitic keratitis, and the consequent deposits in the pupil, or around its margin, are first detected when the cornea is recovering its transparency.

KERATITIS WITH SUPPURATION.

In simple inflammation of the cornea, the opacity, however dense it may be, consists of inflammatory exudation among the lamellæ of the part, without any destruction of the lamellæ themselves. Under certain conditions of the patient's system, however, the inflammation may run a very acute and rapid course, and within a few days terminate in suppuration or ulceration.

When suppuration takes place in the substance of the cornea, it is most frequently at the centre, or a little below that spot, that the pus collects. Its presence is usually manifested by a small yellowish patch in the midst of the general haziness. In very severe cases this yellow patch may rapidly spread, until the whole cornea assumes one uniform creamy tint, entirely hiding every trace of iris; the cornea then softens, and gives way at some part, the iris prolapses, and vision is eventually lost.

These are extreme cases: a more ordinary form of suppuration is that in which the pus gradually infiltrates the lower third, or even the lower half, of the cornea, and at last makes its way through the posterior elastic lamina, and then sinks down to the bottom of the anterior chamber, where it forms what is termed *hypopyon*.¹

The giving way of the posterior elastic lamina of the cornea is sometimes speedily followed by that of the anterior lamina, and in that case a perforation is established, through which a prolapsus of the iris takes place. This perforation of the cornea is followed by immediate relief of the severe pain which had existed as long as the pus was pent up among the fibres of the cornea, or in the anterior chamber. This pain is often severe to a degree quite incredible to those who have never witnessed such cases, assuming the form of neuralgia, and wholly preventing sleep.

Treatment.—In general surgery we are so accustomed, whenever an abscess forms, to regard its evacuation as the very first indication for treatment, that I may be expected to mention a puncture for giving exit to the pus, as the most important step in treating a case of suppuration in the cornea. But, although it is common to speak of *abscess* in this part, the matter is not contained in a distinct cavity, but is infiltrated among the corneal fibres, so that if an incision be made, the pus does not flow out. The cornea, too, differs from every other superficial tissue of the body, in being transparent; and we should avoid inflicting any unnecessary wound, even to the smallest extent, upon a structure, the transparency of which is essential to sight.

[It is now generally admitted that an incision through the suppurating spot will often limit the suppuration and consequently the destruction of the corneal tissue, and give instant relief to pain.—J. W. H.]

¹ This collection of pus at the bottom of the anterior chamber is by some authors termed *onyx*; others use the latter word—now almost obsolete—to signify an abscess in the substance of the cornea.

The general tonic plan of treatment I have sketched out as suitable to cases of common keratitis will be applicable, with certain modifications, to keratitis with suppuration. We must take care not to reduce the patient's vital powers; for, if we do, not only will the softening of the corneal tissue be likely to spread, but if perforation of the cornea takes place, there will be a deficiency of reparative material to fill up the breach, and a large prolapsus iridis, with consequent distortion or obliteration of the pupillary opening, will be the result.

In the very early stage of suppuration, when a small yellowish patch in the midst of the hazy cornea is all that is seen to mark the beginning of suppuration, blistering to the temple sometimes aids in checking the formation of pus; but when a considerable portion of the cornea has become infiltrated, and severe neuralgia sets in, blistering only aggravates the pain. Narcotics must then be given; to children, a few drops of tincture of hyoscyamus at bedtime; to adults, a fuller dose—3ss. or ʒj. In very severe cases of neuralgia in the fifth nerve, hyoscyamus will be found unavailing, and morphia must be resorted to, especially if the patient be accustomed to the use of opium. Sometimes a piece of lint steeped in chloroform liniment, and laid upon the temple and forehead, over the region of the lacrymal and supraorbital branches of the fifth nerve, is of great service in lulling the pain.

If the infiltration and softening of the cornea go on to perforation, the aqueous humour at once drains away, and then the neuralgia usually ceases, or is mitigated in a remarkable degree. If the pain ceases, so as to allow the patient to obtain sleep without the aid of narcotics, they ought, as soon as possible, to be laid aside; for they almost invariably take away appetite, and the patient is now in need of good nourishment to hasten the repair of the breach in the cornea.

Bark and ammonia, or quinine, may be required at this stage of the disease; but a carefully-regulated nutritious diet, with a moderate amount of stimulants, must be the chief sources of the reparative process.

As respects local treatment, protection from light, and occasional fomentation with warm water or poppy-decoction, comprise all that is necessary during the earlier stage. When, however, the cornea has given way, the eyelids must be kept constantly closed, either by the application of a strip or two of plaster, or by means of a light pad of cotton-wool, arranged around the eyeball, and kept in its place by a bandage. The eye should only be opened occasionally by the surgeon, to ascertain the progress of repair. In some cases it is useful to abstain from examining the eye for four-and-twenty or eight-and-forty hours.

When prolapsus iridis has occurred, this occlusion of the eye is especially useful, as, by keeping the parts at rest, an opportunity is afforded for the adhesion of the protruded iris to the edges of the aperture in the cornea. As soon as this adhesion has taken place, no more iris can escape, and the prolapsed portion gradually shrinks, and flattens down to the level of the cicatrix. When, from want of vigour in the patient, the adhesive process is sluggish, it is sometimes useful lightly to touch the prolapsus with a point of nitrate of silver, but there is a risk of the inflammation thus provoked extending beyond the prolapsus.

To attempt to return a portion of iris which has prolapsed through a loss of substance in the cornea, is utterly futile; for it will protrude again and again, so long as there exists an aperture for it to escape through.

Disease of the fifth nerve, caused either by pressure on its trunk, as it is emerging by the side of the pons Varolii, or by primary degeneration of the tissue of the nerve itself, will give rise to a form of keratitis with suppuration very similar to that described in the preceding pages. In the cases of disease of the fifth nerve which I have seen, this affection of the cornea has not come on during the neuralgic stage, but at a later period, when, in consequence of partial or total destruction of the trunk of the nerve, there has been anæsthesia of the parts supplied by the ophthalmic division. In three or four cases which I have watched, the whole cornea was not destroyed; but after perforation had occurred, the process of softening ceased, and reparation so far took place that eventually there remained only an opaque cicatrix

in the cornea, to which a portion of the iris adhered.¹ Two opinions are entertained respecting the relation of the nerve-lesion and the ocular disorder. The ophthalmia and corneal ulceration, following the nerve-lesion, have been regarded by some as direct results of the abolition of a trophic influence thought to be exercised by the fifth cranial nerve over the ocular tissues; an opinion which has its origin in Majendie's well-known experiments. Others have looked upon the ocular disorders as the consequences of mechanical and other direct injuries of the occurrence of which, owing to the anæsthesia of the surface of the eyeball, the sufferer is unaware. This opinion is in harmony with Snellen's experiments, and with the facts within the experience of every ophthalmic surgeon, that in such cases small foreign bodies are not infrequently found upon the cornea or under the eyelids, upon a removal of which and closure of the eyelids the ophthalmia usually subsides, and the ulceration of cornea ceases without further treatment.

'EXANTHEMATOUS OPHTHALMIA' (SO CALLED).

(*Post-febrile ulceration of the cornea; Ophthalmia morbillosa; Ophthalmia scarlatinosa; Ophthalmia variolosa; Ophthalmia erysipelatosæ.*)

The various forms of ophthalmia accompanying the exanthemata have been described by some authors with considerable minuteness; but if we restrict the term ophthalmia to signify an inflammation of the conjunctiva, it is perhaps in measles only that any very marked ophthalmia can be said to occur. Taking place, as it does, at the onset of the attack, it is one of the most marked symptoms of the disease, but demands no special treatment. The really important affection connected with measles, is the *ulceration of the cornea*, which results from the general debility produced by the disease. This ulceration is commonly attributable to a neglect of tonic treatment after the inflammatory symptoms have passed away. Iron and quinine, alone or in combination, cod-liver oil, the various influences of fresh air and nutritious diet, are all to be put in requisition to avert or to heal these ulcerations.

Scarlatina, on account of the greater exhaustion of the powers of life which it induces, is still more likely than measles to be followed by ulcers of the cornea. In some extreme cases of this frightful disease, the cornea lose their vitality, and entirely slough away. The same system of tonics and nutritious diet which I have mentioned as useful in averting the sequelæ of measles, would be still more urgently called for after an attack of scarlatina.

During erysipelas of the head and face, in the severe form, the lids are so completely closed by the swelling of the skin, as to hide the eyes from observation. In the stage of debility succeeding the attack, ulceration of the cornea may arise, as in the two diseases above mentioned; or the cornea may even slough, as in scarlatina.

Of all the exanthemata, small-pox produces the greatest damage to the eyes; and a large proportion of those persons whom we see with shrunken globes, or with their cornea converted into chalk-like cicatrices, have lost their sight from the ulceration introduced by this disease. It was formerly supposed that these opacities were produced by pustules on the cornea itself; but it has been ascertained that pustules never form on this part, the opacities being invariably the result of ulcers, caused by the extreme prostration which succeeds the inflammatory stage.²

¹ In a paper published in the eighteenth volume of the *Medico-Chirurgical Transactions*, 1845, I drew attention to the fact that anæsthesia of the fifth nerve was far more frequent on the *left* than on the right side. In 1857 I forwarded to the editors of the French translation of Mackenzie's *Treatise* (vol. ii. p. 763) a note containing all the literary references to cases of anæsthesia of the fifth nerve which I had collected up to that time. The result of the analysis of fifty-one cases is as follows: in five patients the fifth nerve was affected on both sides; in thirteen the right nerve only was affected; while thirty-three patients had anæsthesia of the *left* nerve.

² For this important fact we are indebted to the extended observations of Mr. Marson, at the Small-pox Hospital. Among 15,000 cases of small-pox, he had seen twenty-six instances of pustules on the eyeball; but they had invariably appeared on the conjunctiva, never on the cornea.

ULCERS OF THE CORNEA.

Under the various heads of *Purulent*, '*Scrofulous*,' and '*Exanthematous Ophthalmia*,' and in the section on *Keratitis*, I have mentioned the more formidable kinds of ulceration to which the cornea is liable. The cases, however, are very numerous in which corneal ulcers are developed in a more isolated manner than in any of the above-mentioned diseases, being unattended with either purulent discharge from the conjunctiva, or general inflammation of the whole cornea.

Persons of all ages are liable to corneal ulceration. It is essentially a disease of debility, attacking those whose general power has been lowered by some exhausting illness, by bad or insufficient food, or some other depressing agency.

In persons of feeble reparative power, an ulcer, instead of healing up to the level of the healthy cornea, sometimes forms a slightly-depressed cicatrix. It is of course most important not to confound these two conditions, as is often done by those unaccustomed to the observation of eye-diseases. A recent ulcer, in which the destructive process is still going on, presents a sharply-cut, well-defined edge, with little, if any surrounding opacity, and the excavation itself, as regards transparency, offers but little contrast to the sound cornea. An ulcer which is healing has a bevelled margin, it is always more or less opaque throughout, and there is a cloudy halo surrounding it; and if the ulcer be large, vessels will be seen running to it from the edge of the cornea. A depressed cicatrix, on the contrary, has its edges smoothly rounded off, and its area is slightly opaque; there is little, if any, cloudy halo surrounding it, and seldom any plexus of vessels going to it from the corneal margin. In some cases, however, a depressed cicatrix is supplied by a small vessel or two, the remains of the plexus which once carried the material necessary for the healing of the ulcer which preceded it.

If the progress of an ulcer be not arrested, it may eventually perforate the whole thickness of the cornea. The aqueous humour then escapes, the iris falls forwards, so that the anterior chamber becomes altogether obliterated, a portion of iris—large or small, according to the size of the perforation—protrudes through the opening, towards which also the pupil is displaced. If the prolapsus iridis be very large, the whole area of the pupil may be annihilated.

In rare cases the ulceration stops short at the posterior elastic lamina of the cornea, which, in consequence of the pressure from behind, is thrust forwards as an almost transparent vesicle, filling up the cavity of the ulcer. The term *hernia corneæ* has been applied to this protrusion. It would at once be distinguished from a *prolapsus iridis* by the retention of the aqueous humour, and the consequent persistence of the anterior chamber.

There is one remarkable form of corneal ulceration of a singularly destructive and intractable character. In most of the cases the patients are persons in broken and unsound health. One eye only is usually attacked; the ulceration commencing at the edge of the cornea, rapidly forms a deep crescentic groove, which continues to deepen and extend itself, until it forms a considerable arc of a circle, and more or less completely isolates the central portion of the cornea, which is left standing up in high relief. Where this central portion eventually yields to the ulcerative process, sight is of course entirely lost. It is remarkable that frequently the posterior lamina of the cornea either remains unbroken, or is perforated to only a small extent. The form of ulceration is very similar to that accompanying gonorrhœal ophthalmia. In one very marked case there was very little pain or uneasiness, and the amount of redness in the conjunctiva and sclerotic was but trifling. Probably some change in the tissue of the vessels supplying the globe was the cause of this rapid and uncontrollable ulceration.

Treatment.—I have said that corneal ulcers are almost always a result of general debility, and therefore their cure is to be sought rather by improving the general power of the patient than by local application. The exception to this rule is formed by those cases in which the ulcer is very large, exhibiting a total want of reparative

action, and by those cases terminating in prolapse of the iris. In both of these instances, the local use of the nitrate of silver is often a very serviceable adjunct to the general treatment. It is most safely applied by touching the ulcer with a fine camel's-hair brush, moistened with distilled water, and rubbed for a few moments upon a clean stick of silver-nitrate. A solution of eserine-sulphate (gr. ij. to ʒj aq.) dropped into the eye sometimes effects considerable improvement.

The mischievous effects of lead-lotions, when applied to ulcers of the cornea, have been already alluded to (p. 35); and solutions of nitrate of silver, if used for too long a time, will also give rise to insoluble deposits, and consequent opacities.

While everything tending to improve the general health is to be resorted to in cases of ulceration, warm fomentations, either simple or of belladonna, and extract of opium, are commonly the best local application. The eye should be kept lightly covered; and if there be intolerance of light, or much pain in the eye, complete closure of the lids is indicated. This closure is especially necessary when either the iris has prolapsed, or a hernia cornea has taken place.

I have already (p. 38) said how useless must be the attempt to push back a portion of iris protruding through a corneal ulcer. If the little nodule of iris soon becomes coated with an opaque layer of adhesive deposit, simple closure of the lids, and support of the general power by suitable diet and tonics, will suffice to cause the protruded iris to become adherent to the edge of the ulcer; after which, no further prolapse will occur. But if the protruding iris, instead of becoming coated with lymph, retains its natural colour and fibrous appearance, a touch with a fine point of nitrate of silver will often set up sufficient inflammation to cause adhesive deposit to take place. In like manner the deep excavated ulcer, which sometimes forms in very anæmic and weakly persons, and threatens to perforate the cornea, or to destroy it by rapidly spreading all around its margin, may be arrested, and a healing disposition given to it, by lightly passing the silver nitrate over the whole excavation and edges of the ulcer.

OPACITIES OF THE CORNEA.

It is of the utmost importance, as respects both prognosis and treatment, that the surgeon should make himself perfectly familiar with the varied appearances which corneal opacities assume. Without this knowledge, he will be constantly liable to deceive both himself and his patient, in promising the removal of opacities which are in their very nature permanent; or in pronouncing incurable, hazy conditions of the cornea, which, if promptly and skilfully treated, may be perfectly removed. To the latter class belong those cloudy opacities which I have described (p. 31) as over-spreading the cornea in the slighter forms of simple keratitis. The short period, a few days or weeks, during which the cloudiness had existed, the presence of a vascular zone in the sclerotic, and some degree of irritability of the eye, would all point out the cloudiness of the cornea as being due to simple inflammatory deposit within its substance, which, under suitable treatment, may be so entirely dispersed as to leave the cornea in all its original transparency. If, on the other hand, the same amount of general haziness were known to have existed for a long time—say a year or more—if there were a total absence of sclerotic redness, and if the eye had long ceased to be irritable, the surgeon would know that the opaque condition of the cornea was incurable, and he would no longer attempt the use of stimulating lotions and ointments, which could only arouse fresh irritation and increase the existing mischief.

The haziness which sometimes remains after a severe and obstinate attack of keratitis, presents an appearance not easy to describe, but which the experience of a few cases will readily enable the surgeon to recognise again. There is a total absence of unnatural vascularity about the eye, but the whole cornea is slightly shaded with a faint haziness, with intervening spaces of almost transparent tissue, through which the colour and texture of the iris and the form of the pupil can be recognised, although not in their natural distinctness. The dimness of sight in these

cases seems to be out of all proportion to the amount of opacity ; and the patient can perhaps merely see black streaks when looking at a page of type.

The terms *nebula*, *albugo*, and *leucoma* have been applied to corneal opacities, according to their different degrees of density ; the slighter forms being distinguished as *nebulae* ; *albugo* and *leucoma* signifying rather the white opacity of cicatrices. The edge of a *nebula* is gradually shaded off into the surrounding clear tissue ; that of a cicatrix, at least one of old standing, is more or less abruptly defined. When a prolapse of the iris has taken place through a corneal ulcer, the leucoma which results is marked in the centre by a small blackish spot.

Treatment.—As regards the prognosis of *nebulae*, their possible improvement mainly depends upon the age of the patient. In infancy, it is quite astonishing to see how the rapid interchange of material which is then going on, will diminish both the extent and the density of even large cicatrices. In an infant attacked with purulent ophthalmia, a cicatrix may at first be so large as to occupy the central third of the cornea, and yet, in after-life, a mere cloudy speck may remain opposite the centre of the pupil. At a later period of life, *nebulae*, which form as the cicatrices of superficial ulcers, are more permanent ; but around the denser part of the speck there is always a certain amount of cloudiness, which slowly disappears. The older the *nebula*, the more sharply defined is its margin.

Allusion has already been made to the permanent white deposit which occurs in corneal ulcers, when lotions containing lead have been employed. The metal is deposited in the state of carbonate, and forms a chalky-white layer on the ulcerated surface. Practice alone can enable the surgeon to recognise these old lead-deposits. They somewhat resemble a little patch of whitewash, their margin being sharply defined, and their surface often presenting minute cracks, through which the tissue of the cornea appears as dark lines. When the ulcer has been very superficial, and the metallic deposit lies just beneath the epithelium, the surgeon may sometimes succeed in scraping away the deposit ; to do this, however, requires the utmost care and lightness of hand.

A very curious form of *calcareous deposit*—phosphate or carbonate of lime—between the cornea and its epithelium sometimes takes place without any previous inflammation. I believe this kind of deposit to be extremely rare, for, since I first noticed it in 1848,¹ I have seen only two other instances. From what I have already said concerning the nature of corneal opacities, the reader will perceive that when they are of old standing, and unconnected with any existing inflammation, local treatment can avail but little. Setting aside those exceptional cases I have enumerated as removable by operation, the partial disappearance of old *nebulae* is due to that change of material which is constantly going on in the human body, and which is so much more active in infancy and childhood than after the period of growth has terminated. The lotions, the drops, the vapours, the ointments, which crowd the pages of the older ophthalmic works, if not actually hurtful, as being likely to set up fresh irritation, are either altogether inert or at best they serve to amuse the patient while time is slowly clearing the opaque tissues.

INJURIES OF THE CORNEA.

Abrasion.—The epithelium covering the anterior surface of the cornea is liable to be torn or scratched by coming in contact with any rough substance ; or a little flap of the epithelium may be partially detached and doubled down. Those who have not seen these slight cases of injury to the epithelium cannot imagine how much pain they produce, especially in persons of a sensitive nervous system. The intimate relations of the epithelial cells and the terminal fibres of the fifth nerve renders this intelligible. A clean cut directly through the cornea often causes far less pain than an abrasion of the epithelium so minute as to be scarcely discernible.

¹ My case was first published in the Appendix to Bowman's *Lectures on the Anatomy of the Eye*, 1840 ; and a second time in my *Guide to the Practical Study of Diseases of the Eye*, 1855.

Within a short time after the epithelium has been injured, the sclerotic is often much injected, and a profuse flow of tears follows every attempt to separate the lids. The surgeon will best obtain a view of the part by placing the patient in a chair and standing behind him. As soon as the lids are widely separated, the pain almost ceases, and the surgeon must then carefully explore the whole surface of the cornea, while the patient moves the eye in various directions, so as to allow a bright light to fall on each portion in succession. A slight irregularity and roughness at one minute spot is often all that can be found to mark the position of the injury.

The *treatment* of these abrasions is very simple. A drop or two of olive-oil or castor oil may be applied to the abraded surface, and then the lids are to be kept closed with a light pad of cotton-wool, and a bandage, or a compress dipped in a solution of extract of belladonna (3j. ad 3viii. aq.), for four-and-twenty hours. As soon as the epithelium is regenerated all irritation ceases, and the uniform polish of the cornea is restored.

Contusion of the cornea.—Blows on the cornea which do not cut or lacerate, but merely bruise, its tissue, vary greatly in their results, according to the violence of the blow, and the age and vigour of the patient. In the severer forms of contusion, softening and suppuration among the fibres of the cornea will probably occur, and the part will afterwards exhibit more or less haziness. But in very feeble or old persons, the whole cornea may become softened and infiltrated with pus, and in such cases the pain is often very severe.

At length the cornea gives way, the aqueous humour escapes, and the pain immediately subsides; but the whole or the greater part of the cornea becomes pulpy and disintegrated, and comes away in shreds, and ultimately the globe shrinks, or else a staphyloma is formed. The worst cases of this kind occur among paupers engaged in stone-breaking. During such work, a pair of gauze-wire goggles should always be worn.

Treatment. Even a slight contusion, if it takes effect at the centre of the cornea, must be regarded as a serious accident, on account of the suppuration and consequent haziness that may possibly ensue. We must take care, therefore, not to reduce the patient by bleeding and mercury, since by so doing the vitality of the cornea is lowered, and softening and suppuration are more likely to take place. An eye which has received a blow on the cornea should be kept closed and defended from light, and poppy fomentation may be used, if any pain comes on. A narcotic may be required at bedtime; and the diet should not be reduced below that which is suited to the patient's ordinary condition.

The setting-in of suppuration, attended as it is with pain, would require an increased dose of the narcotic; and should the cornea give way, a tonic treatment, with a suitable proportion of stimulants, would become necessary, to limit the destruction of tissue, and afford material for repair. In such cases warm fomentations of belladonna and opium and the frequent instillation of eserine-sulphate prove very useful.

Incised and punctured wounds.—Although cuts of the cornea are usually produced by sharp-edged or pointed bodies, they also occasionally result from sudden blows inflicted with blunt ones; and a smart stroke with a stick will sometimes inflict on the cornea a cut as clean as if made with a knife. Wounds of this latter description, however, on account of the shock given to the whole eye, are usually much more serious than those made with sharp instruments. A wound involving one half of the corneal margin, such for instance as is made in the operation of extraction, may become completely united within three or four days, without inflammation occurring in any other tissue of the eyeball, whilst a much smaller cut produced by a blow with a stick or stone will be followed by severe and long-continued inflammation, ending in complete disorganisation of the globe. Small sharp bodies, such as fragments of metal or glass, when driven with great force and rapidity against the cornea, frequently produce so small a wound, that a surgeon unaccustomed to see such cases may be apt to underrate the size of the foreign body which has

inflicted the injury; the elasticity of the corneal tissue causing the wound to contract as soon as the foreign body has passed through. When a case of this kind is seen immediately after the injury, the most careful scrutiny, with all the advantages of a good light, is often required to enable the surgeon to detect the wound. The whole surface of the iris, and especially the bottom of the anterior chamber, should be most carefully examined, in order to detect the lodgment of the penetrating body; and if the cornea be still transparent, and the aqueous humour retained, the pupil may be dilated with atropine, and the lens and deeper tissues explored with the ophthalmoscope. If any portion of the penetrating body protrude from the wound, it should be once extracted with a fine well-closing forceps, the lids being held apart with a spring speculum, and the globe steadied by nipping up a fold of the conjunctiva covering the sclerotic.

When the wound of the cornea is large, a portion of the iris is frequently forced through the wound. If such a case is seen very shortly after the accident, and before there has been time enough for the protruded iris to become united to the margins of the corneal wound by adhesive deposit, the portion of iris may sometimes be returned by careful pressure with a probe or small spatula. In such cases sulphate of eserine has been reported useful. The strong contraction of the pupil which it produces tends, it is believed, to draw in portions of iris which have escaped through a peripheral corneal wound. If, however, adhesion between the cornea and iris has already taken place, this reduction is impossible; and the surgeon must then content himself with maintaining the parts in perfect rest by keeping the lids closed.

Sometimes the protruded portion of iris gradually becomes distended with aqueous humour, and assumes a rounded pouch-like form. This little pouch should be freely punctured, or a portion of it cut off with curved scissors, and the bandage applied as before.

The advice I have here given, as to returning the iris protruding through an incised wound of the cornea, may at first appear to be inconsistent with what I have before said, at p. 38; but the difference between the two cases consists in this—that when an ulcer has perforated the cornea, there is an actual loss of its substance, and if the iris protruding through such an aperture be pushed back, it will escape again and again. But in the case of an incised wound there is no loss of corneal tissue; and if the protruding iris be returned into the anterior chamber, the elasticity of the cornea will bring the edges of the wound into apposition, and keep them so until they have become united.

Punctured wounds of the cornea vary much in their character, accordingly as they are inflicted by means of pointed bodies of a large size, or by such small fragments as remain embedded among the fibres of the part. Wounds of the former class frequently involve other parts of the eye, and penetrate through the cornea into the iris or the lens. These complicated injuries cause eitherritis or cataract, and will be spoken of in future chapters.

The simplest and by far the most common form of puncture of the cornea is that which happens when little fragments of metal or grit are forcibly projected against the eye, and remain sticking either in the epithelium or in the superficial layer of the cornea itself. Engineers, metal-turners, mill-stone dressers, stokers, are constantly liable to these injuries, and the surgeon should be able at once to remove the foreign body without inflicting in the attempt any farther injury on the cornea. Standing behind the patient, who should be seated opposite a window, the surgeon raises the upper lid by placing the tips of his first and second fingers against the edge of the tarsus, beneath the cilia, and then pressing the lid upwards and backwards without everting it; he then with these two fingers steadies the globe by gentle pressure just above the cornea, while the point of the ring-finger gently presses the globe at its inner side. In the other hand he holds a little spatula-shaped instrument (which for want of a better name I have called a 'spud'), the flat end of which he passes under the foreign body, and so tilts it out. The point of a cataract-needle is in a steady practised hand very suitable for extracting these little bodies. All the treatment

necessary after their removal consists in keeping the eye closed for a day or so with a compress and perhaps occasional fomentation.

If an elongated chip of metal strikes the eye obliquely, it sometimes wedges itself into the cornea at about the middle of its thickness, lying exposed to view, but so completely buried as to afford no hold to a forceps. The surgeon must with a cataract-knife or cutting-needle slit up the layer of corneal substance along the whole length of the foreign body, which can then be turned out without difficulty.

One of the injuries most difficult to treat is that inflicted by a sharp-pointed chip of metal just long enough to transfix the cornea, and to thrust its point into the anterior chamber, while the other extremity is so much embedded as to offer no hold for a forceps. If the surgeon attempts to dig out such a chip, he will almost certainly drive it farther in, until at last it slips wholly into the anterior chamber, and entangles itself among the fibres of the iris.

The removal of the foreign body will call for all the operator's skill and patience, and chloroform must be used if the patient be timid and unsteady. The lids being separated with the spring speculum, an assistant fixes the globe by nipping up with a forceps a fold of the conjunctiva at its lower part. The surgeon then, with a broad cutting-needle, makes an opening in the cornea close to its outer margin. The needle should be slowly withdrawn, without rotating it in the slightest degree, so that the aqueous humour may, as far as possible, be retained. Then a small spatula is to be passed in at the opening, and carried quickly and steadily across the anterior chamber, so as to interpose between the lens and the intruding point of the foreign body. The spatula is then to be pressed forward against the foreign body to keep it fixed, while with a cutting-needle held in the other hand, the surgeon slightly enlarges the wound on the anterior surface of the cornea. Still steadying the point of the foreign body with the spatula in the anterior chamber, he endeavours with a very fine and well-closing forceps, to grasp the extremity of the foreign body and draw it out of the wound.

It is preferable to support and fix the foreign body with the broad needle, rather than to withdraw this and replace it with the spatula, because should the aqueous humour escape before the end of the spatula is interposed between the point of the foreign body, which projects into the anterior chamber, there is risk of the lens being injured.

I have had occasion several times to perform this operation, which the minuteness of the foreign body, its close proximity to the transparent lens, and the necessity for limiting the extension of the external wound, combine to render one of the most difficult in ophthalmic surgery.

A foreign body, which passes quite through the cornea, may wound the lens and remain embedded in its substance, producing a traumatic cataract; or it may become fixed in the iris; or, having lost its momentum in traversing the cornea, it may fall down to the bottom of the anterior chamber. Under any of these conditions, if the surgeon sees the case immediately after the accident, while the cornea is still clear, and the iris and anterior chamber are not yet obscured by inflammatory effusions, he should endeavour at once to extract the foreign body. If it can be distinctly seen sticking in the lens, it will be right to make a section of the upper half of the cornea, and remove the lens, as in the ordinary operation for cataract. A chip of metal fixed in the iris may be removed with Assalini's spring-forceps,¹ or the cannula-forceps, introduced through a small corneal wound. It will be often found best to withdraw and excise the small piece of iris, in which the foreign body is entangled. And in the same manner foreign bodies of any kind, which are lying loose in the anterior chamber, may be seized and extracted.

The surgeon must not be deterred from attempting to remove these foreign bodies by the stories he will find in many of the older ophthalmic works, about the oxidation and solution, or encysting of metallic fragments. The lymph which is thrown out

¹ This instrument was invented by Assalini for seizing the iris in the operation for artificial pupil; *Ricerche sulle pupille artificiali*, &c. Milano, 1811. For this purpose it has been superseded by the more delicate *cannula-forceps*.

around a metallic chip in the iris does indeed¹ for a time, encase it and hide it from view ; but this is only the beginning of a tedious iritis, which will probably end in disorganisation of the eye, or, at least, produce obstruction of the pupil and loss of sight.¹

Foreign bodies lying loose in the anterior chamber are to be removed in a similar way to that I have just recommended in the case of bodies fixed in the iris ; the extent of the corneal incision being of course proportioned to the bulk of the body to be extracted.

This may perhaps be the most convenient place to notice those rare cases in which a living entozoon constitutes the foreign body in the anterior chamber.

The *Cysticercus telæ cellulosa* has been repeatedly met with in this situation, as a rounded, semi-transparent, vesicular body, furnished with a long retractile neck, terminating in a head furnished with suckers and a circlet of hooks. If not removed, the animal eventually sets up inflammation of the iris and cornea, which ends in total loss of vision. A crescentic incision along the edge of the cornea allows of the escape of the animal along with the aqueous humour. Cases have been reported by many ophthalmic writers, among whom Mackenzie has given the fullest details, and has figured the animal both in its natural condition and magnified.²

All the operations on the cornea just described will be greatly facilitated by the use of the spring speculum, a forceps to fix the globe, and, in irritable and timid patients, by the administration of chloroform.

The *after treatment* of all the foregoing cases, in which an incision of the cornea may have been necessary for the removal of a penetrating body, mainly consists in keeping the eye perfectly at rest and protected from light, while the healing process is going on. For the first twenty-four hours at least, *both eyes* should be covered with a light bandage. After that period it may be sufficient to keep the wounded eye closed, and the length of time during which this closure should be maintained must depend upon the rapidity with which the wound heals, and the aqueous humour is re secreted—circumstances varying according to the constitution of the patient, and the amount of violence inflicted on the eye by the accident and the subsequent manipulations of the surgeon. Patients should neither be kept low nor over-stimulated, but maintained as near as possible at their natural standard of vigour. Those of an irritable temperament will often require a narcotic for several nights after these operations ; but if chloroform has been used, a narcotic should not be given while the system is still under the effects of the inhaled vapour.

¹ In a case I communicated to the *Dublin Journal of Medical Science* (n. s. vol. vi. p. 210, 1848), a very minute scale of copper remained fixed in the iris for *eight years*, and, after causing repeated attacks of iritis, was at last thrust forwards against the cornea by the effused lymph ; ulceration was set up, and the little fragment, projecting through the cornea, was seized and extracted.

² Mackenzie (*Practical Treatise*, &c., 4th edit. 1854) quotes a case of *cysticercus* in the anterior chamber, observed by Schott in 1830 ; another by Logan in 1833 ; and relates two cases of his own in 1848 and 1850, and two others in the practice of other surgeons. He also mentions a case reported by Appia, in which the *cysticercus* is said to have been seen within the substance of the cornea. In all these instances the *left eye* was affected, and Mackenzie remarks that 'the left has suffered much oftener than the right eye from the intrusion of *cysticerci*, either under the conjunctiva or into the interior of the organ.' Cases which have been reported subsequently to the publication of Mackenzie's work do not, however, bear out this statement. In the *Archiv für Ophthalmologie*, vol. i. p. 453, is a case of *cysticercus* in the *right* anterior chamber ; and in the same journal, vol. iv. p. 113, is another, also in the right eye ; Teale has reported a case occurring in the right eye ; *Ophthalmic Hospital Reports*, vol. v. p. 320. When Mackenzie wrote, *cysticerci* had never been discovered in the *vitreous* chamber ; but in the *Archiv* twenty cases have already been reported, nearly equally divided between the right and left eyes. (See a subsequent note on *cysticerci* on the retina and in the vitreous humour.)

CHAPTER V.

DISEASES OF THE SCLEROTIC.

INFLAMMATION.

Scleritis; Sclerotitis; Rheumatic Ophthalmia.

THE sclerotic is inflamed to a certain extent in all cases of keratitis and iritis, and exhibits that zone of red vessels close around the margin of the cornea which is so marked a symptom of both these diseases. A more extended inflammation of the sclerotic not uncommonly forms one of the complications of catarrhal ophthalmia.

But there is also a form of inflammation which is almost limited to the sclerotic, the conjunctiva being implicated only in a secondary degree, and this sclerotic inflammation may assume either the acute or the chronic form.

In the acute inflammation the whole of the sclerotic is intensely injected the part assuming a peculiar pink tint, quite different from the more vermilion colour of conjunctival inflammation. In very severe cases the pink tint has a shade of violet, in consequence of the depth at which the vessels lie in the fibrous tissue. Intolerance of light and lachrymation are marked symptoms, and in and around the eyeball there is always considerable pain, which sometimes assumes the form of intense neuralgia throughout the ophthalmic division of the fifth nerve, extending even into the second and third divisions.

The attack is attended with general constitutional derangement; the tongue is coated, the appetite bad, and the urine often deposits large quantities of lithates.

Treatment.—The bowels must be first thoroughly cleaned, and then narcotics given, in doses proportioned to the severity of the neuralgia and the former habits of the patient. Half a drachm, or a drachm, of tincture of hyoscyamus may be sufficient in some cases, while in others full doses of morphia will be requisite to insure sleep. In some patients quinine, in others iodide of potassium, is of great service; to those in whom a gouty diathesis is more marked, colchicum given in combination with an alkali will be far more beneficial. The patient's appetite is usually so bad that it requires management to induce him to take sufficient nourishment. Beef-teen, bread-and-milk, and various modifications of farinaceous food, are often more readily taken than solid meat. Sugar should be avoided, and beer as containing sugar, dry wine or diluted spirit being substituted, and of course only given in quantities demanded by the condition and previous habits of the patient. Local depletion by means of leeches seldom produces more than temporary benefit, and blisters only aggravate the neuralgia. Steaming the eyes over hot water is usually soothing, and preferable to fomentation, in consequence of the extreme irritability of the surface of the eye. A very effectual local application is chloroform, diluted with olive-oil according to the susceptibility of the skin, and applied on lint to the temple and forehead. The patient's room should be moderately shaded from light, and the eyes still farther protected, if necessary, by a suitable eye-shade, or tinted spectacles; but complete darkening of the room is unnecessary, and it has the great disadvantage of rendering the examination of the eyes by the surgeon intensely painful during the abrupt transition from darkness to light.

Chronic inflammation of the sclerotic occurs frequently, but by no means exclusively, in rheumatic subjects. Instead of involving the whole extent of the sclerotic at once, it commonly appears as a limited patch of redness, close to the cornea, after a time fading away, and then reappearing on some other portion of the white of the eye, but always keeping close to the corneal margin.

When this chronic inflammation of the sclerotic has gone on for a long time, it has a tendency to involve either the cornea or the iris. In the latter case the iritis is so insidious and so slightly marked as frequently to be overlooked; and it is not

until after the sclerotic redness has wholly disappeared that some dimness of vision induces the surgeon to make a careful examination of the pupil; when he will probably detect some small adhesions between the iris and the capsule of the lens, or a filmy opacity of the latter, dotted with minute patches of pigment.

It appears to be this form of obstinate sclerotic inflammation which Wilde¹ and others have described as 'inflammation of the ciliary body, ciliaritis.' No evidence, however, exists that this structure is specially the seat of inflammation; indeed, in most instances perhaps the subconjunctival areolar tissue and fascia are principally implicated, the sclerotic being only subordinately and very superficially involved. For such cases the term episcleritis used by some authorities is very appropriate. Episcleritis is most frequently seen in youths and young adults of feeble delicate constitution. It sometimes begins as a phlyctenula, which, instead of fading away as in ordinary phlyctenular ophthalmia, increases, extending the area of its base until it forms a low pink hummock-like swelling seated upon the sclerotic. Where the episcleral structures alone are implicated, or the sclerotic is only very superficially involved, upon the resolution of the inflammatory swelling no traces of the disorder remain; but, where the sclerotic has been more deeply affected, it is not infrequently found thin and blue after the swelling disappears.

Treatment.—Chronic inflammation of the sclerotic is a very tedious affection, and one that is extremely liable to recur, if the patients are exposed to cold and damp, or fall into that dyspeptic condition which induces chronic rheumatism. Strict attention to diet, avoidance of sugar, and substances which form sugar in the system, a dry and temperate climate, will be the best means to prevent the sclerotic inflammation from becoming periodical in its return. Quinine is commonly the most effectual remedy, and small flying blisters to the temples are often valuable adjuncts. But if the patches of redness shift about from one side to the other, fading away at one part only to reappear at an opposite point of the globe, a vigilant watch should be kept upon the iris, lest it should be attacked with inflammation. If the pupil becomes sluggish and slightly irregular, a careful examination with concentrated light will probably reveal a very slight, barely perceptible, deposit of lymph fringing the pupillary margin. The sight will at the same time be more or less cloudy. In such a case recourse must be instantly had to atropine, and mercury or potassic iodide must be carefully given to check the *iritis*. The mouth must never be made at all tender, and the depressing influence of the mercury may be counteracted by a daily dose of bark, and a moderately nutritious diet. The bark should be continued in small doses for some weeks after the mercury has been left off.

INJURIES OF THE SCLEROTIC.

Clean cuts of the sclerotic, inflicted with sharp bodies of various kinds, frequently involve the subjacent structures, the choroid and retina. If the latter be extensively divided, a greater or less quantity of the vitreous humour is almost sure to be lost. The laxity of the conjunctiva, however, often serves to limit the escape, as the tenacious fluid becomes entangled among the meshes of the subconjunctival areolar tissue.

The prognosis of wounds of the sclerotic depends upon their extent, the amount of vitreous humour which has been lost, and, above all, upon the fact whether or not the foreign body inflicting the wound has penetrated into the interior of the globe. The wound made by the entrance of a grain of shot is usually very small, as the elasticity of the sclerotic causes its fibres, after being separated by the shot, instantly to close up again, as soon as it had passed through them. When quite recent, a shot-wound in the sclerotic is hidden by a little patch of blood extravasated beneath the conjunctiva. The entrance of a grain of shot, or a fragment of metal, through the sclerotic into the vitreous chamber is almost certain to set up a slow inflammation of the whole globe, ending in loss of sight and atrophy of the organ.

¹ *Medical Times and Gazette*, n. s. vol. ix. p. 515, 1854.

Simple punctures and small cuts through the sclerotic, unattended with the retention of any foreign body, commonly unite very well, provided the eye be kept in perfect rest, and the reparative process be not interfered with, and checked by injudicious applications, or by general depletion and weakening of the patient's system. If extensive and gaping, and not complicated by the presence of a foreign body, the wound may be closed with a suture of the finest China silk passed through the episcleral tissues. It seems almost superfluous to insist upon the necessity for absolute repose for the wounded organ; and yet it is wonderful to see how the good sense of the surgeon, who would treat a fractured limb on the principle I have just mentioned, seems to desert him as soon as a wounded eye comes under his care.

Rupture of the sclerotic, with displacement of the lens.—A very remarkable injury sometimes happens to the sclerotic, consisting in a laceration extending completely through its substance, within a line or two of the corneal margin, while the conjunctiva remains unbroken, and the dislocated lens, slipping out through the rent in the sclerotic, becomes firmly wedged beneath the conjunctiva.

This rupture of the sclerotic always takes place on the side of the eye opposite to that which has received a severe blow with some blunt body; the fibres, being suddenly put on the stretch, give way at the point where they are the most bent. Hence it is that the seat of rupture is almost always either the upper or the inner part of the globe, the lower and the outer portions being comparatively exposed to violence, while the prominence of the eyebrow above, and of the nose internally, defends the upper and the inner portions.

Rupture of the sclerotic, with sub-conjunctival dislocation of the lens, is always attended with some injury to the iris. Either that portion adjacent to the sclerotic wound is drawn into it, the pupil remaining large, and displaced towards the margin of the cornea, or else the shock causes the ciliary attachment of the iris to give way, to a greater or less extent.

It sometimes even happens that the whole ciliary attachment gives way, and the entire iris is driven completely out of the globe, through the rent in the sclerotic, along with the aqueous humour, lens, and a portion of the vitreous body. This large escape of the contents of the globe only takes place, I believe, when the conjunctiva is also ruptured.¹

When a recent case of ruptured globe is seen soon after the infliction of the injury, the parts are so obscured by blood that it is often impossible to form a correct estimate of the damage the globe has sustained. Detachment of the iris from its ciliary connection is always attended with bleeding, which may completely hide everything behind the cornea. The lens, too, if dislocated beneath the conjunctiva, is often enveloped in blood, so that its form cannot be precisely defined. Until the blood behind the cornea has been absorbed, it is impossible to ascertain whether the retina has retained its function; so that in every case the prognosis will be extremely doubtful.

Treatment.—If the detached iris is hanging out of the wound through a rent in the conjunctiva, it should be snipped off with scissors; but, inasmuch as the lens, if lying between the unbroken conjunctiva and the sclerotic, may be so obscured by effused blood as to be with difficulty recognised, it will be well to wait a few days until the blood has become absorbed, and then the division of the conjunctiva covering the displaced lens will allow of its easy removal; severe as this injury appears, recovery with very useful sight has been not infrequently observed.

Absolute rest of the eye is the one important point in the treatment of all cases of ruptured globe. For the first few days, both eyes should be kept closed, by means of strips of plaster or a light bandage. Afterwards, it will suffice to close the injured eye only; but this closure should be uninterruptedly maintained for a week or ten days.

¹ See two cases in which the lens and iris were driven out of the eye through the ruptured sclerotic, published in my *Practical Guide, &c.*, 2nd edit. pp. 388-9. Also a case of sub-conjunctival dislocation of both lenses in the same person, p. 118, note.

The patient should not be kept on low diet, nor depleted in any way; least of all should he be brought under the action of mercury, as is too often done. Such treatment can only have the effect of lowering his reparative power, and so retarding the process of cure.

CHAPTER VI.

DISEASES OF THE IRIS.

CONGENITAL DEFECTS.

(*Irisæremia; Coloboma; Misplaced pupil; Persistence of membrana pupillaris.*)

CONGENITAL absence of iris (*irideremia*) always attracts the notice of those about the infant by the peculiar reddish glow which is reflected from the retina. The child seems to shrink from strong light, and there is a good deal of unsteadiness of the globes. The whole space behind the cornea presents one uniform red or orange tint, while the edge of the lens is marked out by a ring of golden light.

Such cases are peculiarly interesting to the physiologist, because they demonstrate that the iris is not an essential factor of accommodation.

Although the term *irideremia* would imply a total absence of iris, a slight rudiment of it is often found, forming a very narrow segment of a circle, skirting some portion of the edge of the cornea.

Considering that a certain number of infants affected with this rare malformation are yearly brought for an opinion to our public eye-hospitals, it is singular that an adult thus affected is so seldom met with. I can only remember to have seen one such case, a short notice of which I published several years ago.¹

Coloboma.—This congenital malformation is the result of an arrest of development, whereby the fetal eye-cleft is incompletely closed. The pupil, therefore, presents an elongated form, and extends down to the lower edge of the cornea.

A median fissure of the lower portion of the choroid and retina, and in some instances of the sheath of the optic nerve, accompanies *Coloboma iridis*. The iris and choroid being formed in the embryo from one vascular membrane curved upon itself, an arrest of development causes in both structures the same kind of defect along the median plane of the eyeball.

Coloboma iridis, however, is not always placed exactly on the median plane of the eye, but sometimes a little to the inner or outer side of it. It usually co-exists in both eyes, although not always in the same degree. Sometimes, instead of the pupil being prolonged down to the bottom of the cornea, an abortive attempt, as it were, to form a coloboma is evidenced by a puckered groove in the iris, extending downwards from the lower edge of the pupil. The actual size of the pupillary aperture in coloboma is not always quite so great as, on a superficial inspection, it appears to be; for the extreme edge of the aperture, when minutely examined, will sometimes be found to be fringed with a blackish-brown pigment; and this at first sight produces the effect of a larger area than really exists.

An old prolapse of the iris through an ulcer, situated at the lower edge of the cornea, by drawing the pupil directly downwards, may produce an appearance a good deal like a *coloboma iridis*. The white cicatrix, however, in the former case, would always enable the careful surgeon to recognise the true character of the deformity.

Another abnormal condition of the pupils consist in their being placed near the

¹ *Guide to the Practical Study*, &c., 2nd edit. p. 400. Samuelson describes a case of *irideremia* in a man of forty-eight. Not only were the irides absent, but the closest scrutiny failed to detect any ciliary processes. His accommodation seems not to have been tested, but he asserted it to be perfect.—*British Med. Journal*, 1863, p. 496. In the *Monatsh. für Augenheilk.*, 1866, *irideremia* is noticed as existing in a woman of forty-two. Her eldest child had the same defect. Hulme reports a case in a man aged twenty-two. He could read No. 6 of Jaeger's test-types.—*Med.-Chir. Trans.*, vol. xlv. France gives another case, a woman aged twenty-three.—*Guy's Hospital Reports*, vol. vii.

margin of the cornea, instead of opposite to its centre. Malposition of the lens appears frequently to accompany this eccentric position of the pupils.¹

Persistence of the fetal *membrana pupillaris* has been described as sometimes causing an obstruction in the pupil which might be mistaken for congenital cataract ; but no practised observer could make such a mistake ; for the *membrana pupillaris* is attached, not to the margin of the pupil, but to the anterior face of the iris, at a little distance beyond, where a more or less elevated ring of small tufts or nodules marks the lesser circle of the iris. Projecting from this part of the iris, I have occasionally seen slight vestiges of the pupillary membrane, in the form of little spurs or tags.

The persistence of any portion of this membrane, even in young persons, is a circumstance of extreme rarity. Dr. Cohn, in the *Klinische Monatsblätter für Augenheilkunde*, 1867 (p. 62), enters into an analysis of the cases published by different authors, and dismisses all of them except five as originating in a faulty diagnosis. He describes four cases from his own observation. I think there can be no doubt that, in most of the instances reported, old adhesions, the result of bygone iritis, have been mistaken for shreds of the *membrana pupillaris*.

[I believe these cases to be much less infrequent than was formerly supposed.—J. W. H.]

The following case appears to be worthy of record, as exhibiting a vestige of the pupillary membrane in a person of middle life.

In the summer of 1867, a lady, aged 30, consulted me for short-sightedness. The case was a very simple one, the myopia not in any high degree, and suitable glasses were all she required. I noticed a fine hair-like thread running obliquely across the pupil of the right eye, and at once recognised it as a vestige of pupillary membrane. It gave the patient no inconvenience, and indeed she could not be made aware of its existence under any illu-

FIG. 5.

mination I could apply. Fig. *a* represents the eye with the pupil in its natural state, and Fig. *b* after atropine. I had expected to find that, as the pupil dilated, while the two sides of the iris were held together by the little thread, the aperture would become irregular ; but this was not the case to any appreciable extent. The iris, of a thoroughly healthy appearance, was of a rust-brown, and the filament was only a little paler in colour. At each end it had a bifid attachment, and looked like a portion of the proper fibrous tissue of the iris drawn out into a thread. Under the ophthalmoscope the media and fundus of the eye presented nothing unusual.²

In the *Albino* the iris partakes of the general want of coloured pigment which characterises the hair and skin. The layer of opaque pigment, termed *uvea*, is altogether wanting, and the structure of the iris presents a singular appearance, as if loosened by maceration. Whitish fibres are intermixed with others of a lilac colour, and through the whole attenuated iris the light reflected from the fundus of the eye transmits a reddish glow.

Albinism is frequently attended with defective vision, and always with great intolerance of light. In some cases, however, sight is very good, and extreme sensibility to light is the only thing complained of.

FUNCTIONAL DISORDERS.

Mydriasis ; Myosis.

Mydriasis.—The pupil is dilated and nearly, or quite, motionless. It may be due to some defect in the retina, optic nerve, or its cerebral connections ; or to some

¹ Figures of unusually extensive coloboma iridis, and of congenital malposition of the pupil, illustrate a paper of mine in the *Ophthalmic Hospital Reports* for 1868 (plate iv. figs. 2 and 3).

² This case was published in the *British Medical Journal*, March 20, 1869.

disturbance of the ciliary nerves inhibiting the fibres of the taira distributed to the sphincter papillæ, or exciting the fibres of the fifth and sympathetics distributed to the radial muscular fibres of the iris, or, lastly, to a direct injury of the iris, as where mydriasis follows a blow on the eye, in which case, not very infrequently, small lesions in the iris are apparent upon inspection under oblique illumination. Mydriasis is often associated with palsy of the ciliary and of the external ocular muscles in lesions of the third nerve. The treatment of mydriasis is that of its cause; locally, eserine may be used.

Myosis.—The pupil in advanced age is naturally small, and its dilatability much less than in early life. It is not to this condition, but to the contracted rigid state of pupil depending on disturbance of innervation, that the term *myosis* is properly applicable. Many cases of myosis, as pointed out by A. Robertson, are attributable to lesion of the cervical sympathetic inhibiting the fibres supplied from this to the dilator pupillæ. In such cases the pupil is small and does not respond to light, but within narrow limits it distinctly dilates and contracts in concert with efforts to accommodate.

INFLAMMATION OF THE IRIS—IRITIS.

Before entering upon this very important subject, it will be desirable to say a few words about the appearances which the iris presents in a healthy state; for it is subject to many variations as to colour and mobility, which, if not rightly understood, may lead to serious errors of diagnosis; mere congenital peculiarities, or changes incident to age, being mistaken for signs of disease.

The iris presents every shade of bluish-grey and brown among the fair and the light-brown races of mankind; whilst among the negro races it is uniformly found of a dark brown, approaching to black. A parti-coloured iris is not very rare; a fourth, a third, or even half of its surface being brown, and the rest bluish-grey; or one iris may be wholly brown, and the other as entirely grey, each eye being perfectly normal in respect of sight. Light-brown irides are often marked with two or three isolated tufts of dark pigment, and these spots are frequently causes of alarm to those who are the subjects of them.

A very slight tremulous vibration of the whole iris attends every movement of the eyeball in some persons, who nevertheless enjoy good sight; but this tremulousness must be regarded as morbid, whenever it exists to any great extent. It is quite independent of the movements of the pupil, and is best seen when that aperture is contracted, as a larger extent of iris is then open to observation. As a decided morbid appearance, tremulousness of the iris is familiar to us in association with fluidity of the vitreous humour.

The pupil is not placed precisely in the centre of the iris, but a little nearer to the median plane of the body; so that the iris is rather narrower between the inner edge of the pupil and inner margin of the cornea than on the outer side of the pupil.

Any considerable deviation of the pupil from a circular form may be regarded as the result of disease; but the pupil may exhibit, especially in elderly persons, a slight irregularity of outline, without any disease having existed in the iris.

The mobility of the iris becomes less as age advances; and, in old people, we often find a small and almost fixed pupil, the sight remaining excellent. In examining the mobility of the pupils, each one should be tested separately, the other eye being closed; for such is the sympathy between the two organs, that when, in consequence of disease in the nervous apparatus, an eye has become quite insensible to light, its pupil, otherwise motionless, will contract whenever light is admitted to the sound eye.

The earliest mention of *iritis* occurs in a treatise by Schmidt, describing the inflammatory changes consequent upon cataract-operations as performed in his day.¹

It is impossible to overrate the importance of inflammation of the iris; for when we consider that the visual function of the eye ceases if the small aperture of the

¹ *Ueber Nachstaar und Iritis nach Staaroperationen*, 1801.

pupil becomes closed, we at once appreciate the consequences of inflammatory effusion into its area.

The attention which has been bestowed upon iritis by ophthalmic writers has led many of them to indulge in minute and tedious subdivisions of the disease, and to distinguish them by complicated terms, which only serve to embarrass and confuse the practitioner.¹

This passion for subtle refinements and nomenclature has been comparatively rare with English writers; and those whose practical experience has been the most extensive have made use of the simplest classification.

There are certain signs common to all cases of iritis, under whatever constitutional modifications it may be developed; such are, a well-marked sclerotic zone of injection; diminished mobility of the pupil, with more or less change in its form; a loss of the lustre and peculiar fibrous appearance of the iris; and a change in its colour.

Other signs mark the peculiar constitutional influence which has given rise to inflammatory action in the part. These will be noticed under the proper heads.

TRAUMATIC IRITIS.

Incised wounds of the iris are not the injuries which cause the greatest amount of inflammation in its tissue. On the contrary, clean cuts, even if very extensive, produce but little inflammatory reaction; while bruising, or continued pressure of the part, such as occurs in certain displacements of the lens, invariably gives rise to inflammation and adhesive deposits.

The wounds which are sometimes inflicted on the iris during the operation for extracting a cataract, or those which are made to form an artificial pupil, are rarely followed by iritis; and when, after a few days, the eye is examined, more or less blood may be found at the bottom of the anterior chamber, but the fibrous tissue of the iris will present almost its ordinary aspect.

The lodgment of a foreign body, however, even of the smallest size, always sets up iritis, which does not permanently cease until the foreign body has been removed. As foreign bodies, before reaching the iris, must have passed through the cornea, I have thought it best to treat of them in Chapter IV., under the section 'Injuries of the Cornea.'

A singular accident which sometimes befalls the iris may be mentioned in this place, although it is really attended with very little iritis, namely, detachment of the iris from the ciliary ligament. The organic connection between these two structures is so slight that a smart blow with a stick or a whip, the rebound of a twig, or the shock of a spent shot, is sufficient to sever them from each other; the extent of the separation varying in every possible degree, from a mere hair's-breadth to the complete detachment of the whole iris from its ciliary connection.

A very slight separation may almost escape notice. It appears as a small, black, elongated mark, close to the extreme edge of the cornea. In proportion to the extent of the separation will be the amount of deformity of the pupil; and when half of the circumference of the iris has been detached, the pupil will probably fall together and be wholly effaced.²

In all extensive cases of detachment, there is bleeding into the anterior chamber; sometimes to such an amount as at first to conceal the injury from view.

Unfortunately the surgeon can do very little in these cases. To replace the detached iris is utterly impossible, and vision must inevitably remain greatly impaired; but at least he can abstain from attempting to hasten the absorption of

¹ For remarkable instances of this mania for subdivisions and uncouth names, see the work of Von Ammon, *De Iritide*, 1836; and that of Rau, *Die Krankheiten und Bildungsfehler der Regenbogenhaut*, 1844.

² The appearances presented by separation of the iris from its ciliary attachment may be seen in most of the illustrated ophthalmic works. I may instance Mackenzie's *Treatise*, 4th edit. p. 306; Cooper, *On Wounds and Injuries of the Eye*, 1859, pp. 170, 173, 175; Lawson, *Injuries of the Eye, Orbit, and Eyelids*; 1867.

the effused blood by administering mercury. It may seem unnecessary to caution any one against such practice, but, in fact, the dogma that 'mercury induces absorption' is so firmly fixed in some minds, that instances are constantly occurring of patients being actually salivated as a means of promoting the absorption of blood which is filling the anterior chamber after rupture of the iris. The rational mode of treatment is to defend the eye from strong light, and to keep the general vigour of the patient up to a healthy point, and then nature will in due time completely absorb the blood, without any aid from drugs.

I have observed how readily the iris inflames when subjected to long-continued pressure. The most striking examples of this are seen, when, in consequence of a blow upon the eye, the lens has been loosened from its connections, and partially dislocated into the pupil. The traumatic iritis is still more severe, if there be, at the same time, an incised wound of the cornea. In that case, the aqueous humour drains away, and, in consequence, the iris becomes compressed between the cornea and the displaced lens. Inflammation of the iris soon sets in; vessels become visible in its tissue, and lymph is effused into the pupil, into which the lens is bulging. The cornea becomes hazy, and is traversed by vessels. The sclerotic and conjunctiva are deeply injected, and there is abundant secretion of tears. If the case be left to itself, or injudiciously treated, the pupil becomes eventually closed with effused lymph; or else the cornea softens and gives way. Meantime the deep tissues become disorganised, and, after protracted suffering, the patient finds the eye utterly useless.

The only way to anticipate all this mischief is to remove the displaced lens, which is acting like a foreign body. To do this requires much tact and care, and, in making the requisite opening in the cornea, the surgeon must endeavour to avoid isolating any considerable portion of corneal substance between his incision and the wound already existing in the cornea, lest the isolated portion should slough from interrupted nutritive supply. Sometimes the wound in the cornea is so placed that the surgeon, by enlarging it, can make an opening sufficient for his purpose. But if the wound be in the centre of the cornea, it is usually desirable to make the incision in a new portion, and as near the margin as possible. If the substance of the lens has been much broken by the original injury, the greater part of it will probably escape when pressure is applied; but if the lens be almost entire, it must be broken up as much as possible before any attempt at pressure is made. The use of the scoop will greatly facilitate the removal of the disintegrated lens, the pulpy substance escaping along the groove. In some cases the removal of a portion of iris will not only facilitate the removal of the lens with the scoop, but will prevent the occurrence or continuance of iritis.

The success of such an operation will depend upon its being performed soon after the accident, while the cornea is still clear, and before iritis and effusion of lymph have set in. If performed at a later period, there will be greater risk of vitreous humour being lost. In all cases the success of the operation, as regards restoration of sight, must be very doubtful; and if performed at a late period, relief of pain, and prevention of complete disorganisation of the globe, will probably be the best result that can be hoped for.

The treatment, after such an operation as I have just noticed, will be similar to that after an ordinary case of extraction of a cataract. Closure of both eyes for four or five days will be necessary, and the reparative powers of the patient must not be depressed by privation of due nourishment.

The surgeon must not deceive himself with the belief that in these cases of wound of cornea, with displaced lens, the administration of mercury can avert destructive inflammation. The efficacy of mercury in controlling the effusion of lymph in non-traumatic iritis, arises from the fact of there being, in that case, no foreign body—which a displaced lens really is—pressing against and irritating the iris. *Traumatic iritis*, set up by a displaced lens, is wholly beyond the powers of mercury, and its administration can only do harm, by lowering the patient's reparative power, and so unfitting him to recover from the operation, should removal of the lens be ultimately resorted to.

RHEUMATIC IRITIS.

Rheumatic inflammation of the iris assumes either an *acute* or a *chronic* character. In the former case, the attack can usually be traced to exposure to cold wind or damp, when the body has been exhausted by fatigue or greatly overheated.

According to the nervous susceptibility of the patient, the onset of an attack of rheumatic iritis will be attended either by dull pain in and around the eyeball, or by acute neuralgia throughout the first division of the fifth nerve, extending even to the second and third divisions.

When the attack is severe, there is usually a good deal of intolerance of light, and lachrymation. The vascular zone is not well marked, on account of its being lost in the general injection of the whole sclerotic, which assumes the purplish tint I have described as characterising sclerotic inflammation.

Rheumatic iritis is almost always attended with some slight haziness of the cornea, and in this respect it differs remarkably from the syphilitic form, which, even in the most severe cases, often leaves the cornea perfectly clear. The morbid changes in the iris itself are sometimes so slightly marked as to escape an unpractised or a careless observer; so that it is not until the inflammation has subsided, and the cornea has become quite clear, that the still-existing impairment of sight causes a more careful scrutiny of the pupil to be made, and then inflammatory exudation into its area, and adhesion of its margin, are found to have taken place.

In the more acute form of rheumatic inflammation, the veins of the iris may be traced on various parts of its surface, as delicate red lines, diverging from the edge of the pupil to the periphery of the iris. I need hardly say that these fine vessels cannot be traced if there exists any considerable haziness of the cornea.

The pupil is contracted, more or less irregular, and as the inflammation goes on, this irregularity becomes more marked, in consequence of effusion of lymph¹ taking place between the edge of the pupil and the capsule of the lens. The insidious manner in which this fibrinous effusion occurs affords a marked contrast to the rapidity with which large masses of yellow or reddish-yellow lymph show themselves on the edge of the pupil in syphilitic iritis.

I have already noticed the neuralgia throughout the region supplied by the ophthalmic division of the fifth nerve, which attends an acute attack of rheumatic iritis. There is also very frequently considerable febrile disturbance, the urine being loaded with lithates.

The majority of cases do not present such acute symptoms as those just described, but pursue a more chronic course. The injection of the sclerotic being less general, the vascular zone around the cornea is better marked, there is little, if any, intolerance of light or lachrymation, and instead of severe neuralgia in the fifth nerve, there is only a dull aching pain in and around the eyeball.

But, whether the iritis be acute or chronic, there is still the same danger of effusion of lymph into the area of the pupil, and this danger is, as I have said, all the greater on account of the gradual and insidious manner in which the effusion takes place. To check this is the main object to be kept in view.

Treatment.—If the early stage of acute rheumatic iritis be attended with severe neuralgia, as is frequently the case, the treatment will be much the same as that which I have described in Chapter V., as suitable to acute inflammation of the sclerotic. In some patients iodide of potassium, in others colchicum, will be of most service; while some cases, characterised by visible enlargement of the veins of the

¹ In describing iritis, I shall frequently have occasion to speak of that exudation from its vessels which constitutes the most serious feature of the disease, by forming adhesions between the papillary margin and the capsule of the lens, or wholly blocking up the area of the pupil with opaque membrane. Whether this *exudatum* becomes itself converted into fibrous tissue, or whether it only influences the cells of the tissue among which it is effused, and causes new cells to be developed from those already existing, is a physiological question which can hardly be decided. I have used the term 'lymph' to describe this *exudatum*, because the word is familiar to all my readers, and is sanctioned by long usage.

iris, yield to turpentine. I have usually given the Chian turpentine in substance, as pills, four grains three times a day. The condition of the pupil must be carefully scrutinised from day to day; and if it be found irregular and angular, or if any brownish tags appear to be forming at its edge, mercury must at once be given. Two grains of calomel, with a third or half a grain of opium, may be taken night and morning; and should any tenderness of the gums begin, the quantity ought at once to be diminished, for if salivation be allowed to occur, the neuralgia is almost certain to return, and the mercury, which in small doses was so beneficial, begins at once to exert its depressing influence. In delicate subjects it is often very useful to give a dose of bark—Battley's liquor cinchonæ or quinine—in the middle of the day, during the time the mercury is being taken. The pupil is to be kept under the action of atropine.

It is almost impossible to lay down precise rules about diet. It should not be low—that is to say, innutritious—but light and easily digestible: soup, bread-and-milk, farinaceous food of various kinds, with or without a proportion of meat, according to the patient's digestive powers and previous habits. Stimulants should be given only in such quantities as may be necessary to sustain the circulating forces. Feeble and depressible persons may require a certain amount of dry wine, or diluted spirit, while those addicted to habitual indulgence may only eliminate the rheumatic poison which they have stored up in their blood, by abstinence from the alcohol and sugar they have so long abused.

Occasional steaming of the eye over hot water is the most soothing local application, and where neuralgia is present fomentation by means of compresses wetted with a watery solution of extract of belladonna and opium will often afford relief.

Leeches to the temples may occasionally be found useful at the onset of an acute attack where there is great congestion; but where neuralgia exists they commonly do harm, and they should never be applied to feeble and depressible subjects, or those liable to erysipelas. Blisters also have the disadvantage of exasperating neuralgia. They are, however, very serviceable in the chronic form which often succeeds the acute attack, and they certainly aid in removing that haziness of the cornea, which, if not promptly dispersed, is apt to become permanent.

SYPHILITIC IRITIS.

Inflammation of the iris originating in syphilis is very frequently associated with other forms of secondary or tertiary disease, especially with eruptions on the skin. It is by far the most marked kind of iritis, and is characterised by a tendency to rapid and abundant inflammatory exudation on the iris, especially about the edge of the pupil, in which situation yellow, reddish-yellow, or nearly red nodules, gummata, sometimes attain to such a size as almost to close up the pupillary area.¹

The cornea is either clear, or marked throughout its lower half by very minute dots, of a pale buff tint. These dots are as small as if pricked in with a point of a pin, and are so closely set together as to suggest to a superficial observer the idea of a faint cloudy haze. It often happens, however, that even these minute dots are wholly absent, and the cornea, during an acute attack of iritis, remains perfectly transparent.

There is always a vascular zone in the sclerotic, but not that generally diffused redness of the eyeball so frequently present in rheumatic iritis. Neither, as a rule, is there intolerance of light, which is one of the most marked symptoms of the rheumatic form.

Irides which have naturally a bluish tint, when attacked with syphilitic inflammation, appear more or less green. This is caused by the presence of yellow serum in the aqueous humour, the admixture of the yellow and blue forming, of course, a green tint. This fact may be demonstrated in some of those old cases in which

¹ In Sichel's *Iconographie* (pl. xiii. fig. 5) is a good representation of a mass of lymph, reddened with vessels, at the edge of the pupil.

chronic iritis has attacked an eye again and again, until sight has been lost, nearly all the tissues having undergone a morbid change. If in such a case the cornea be carefully punctured with a broad needle, and the fluid of the anterior chamber caught in a spoon, the application of heat will at once show the presence of albumen; and if the iris have been originally bluish, that colour will be restored as soon as the last drop of the yellow fluid has drained away from the anterior chamber.

When a patient has syphilitic iritis for the first time, it may attack both eyes together, or may be limited to one eye. When relapses occur, the inflammation usually affects the right and left eye alternately; and these attacks may come on without the patient having contracted any fresh primary disease.

Syphilitic iritis is so much modified by the condition of the patient, that the surgeon must take care not to form to himself any arbitrary idea of the appearances, or expect to find in every case the strongly-marked and unmistakable proofs afforded by large nodules of exudation around the pupil. In fact, iritis may exist to such an extent as to produce serious and permanent obstruction to the pupil, without any development of these nodules. In some cases the lymph is uniformly distributed around the margin of the pupil, which then assumes a thickened ring-like appearance, the rest of the iris exhibiting little, if any, deviation from its healthy aspect. The loss of its mobility, however, is always well marked, even in the slighter cases; and, indeed, the sluggishness or total immobility of the pupil, when exposed to light, is one of the most valuable diagnostic signs of iritis in its early stage.¹

Occasionally the nodules of lymph, instead of appearing on the edge of the pupil, are situated on the greater circle of the iris, in the re-entering angle formed between it and the cornea. Such cases are comparatively rare.

In every case of iritis, the surgeon should most carefully examine the area of the pupil, to determine whether it be or be not overspread with lymph. This sometimes exists merely as a very thin film, which may escape detection, unless light be concentrated upon it by means of a lens of short focus. Such a film, however, if not speedily removed by proper treatment, will rapidly become thickened by fresh deposits, and, growing more and more opaque week by week, will eventually form a serious obstacle to the transmission of light.

The so-called 'closure of the pupil,' justly regarded as the most serious termination of unchecked iritis, is caused partly by the nodules of lymph which are thrown out upon the margin of the pupil, and unite it to the capsule of the lens (*synechia posterior*) and partly by exudation of the same inflammatory kind, which overspreads that portion of the capsule corresponding to the pupillary area. This exudation forms organised connections with the nodular deposits on the edge of the pupil, and eventually, by its contraction, draws the margin of the pupil together, and permanently blocks up its greatly diminished space with a tough, firm, and opaque membrane.²

Treatment.—From what has been said, it will be seen that the leading principle in the treatment of syphilitic iritis consists in procuring as quickly as possible the absorption of the exudation which has been effused in and around the pupil. To effect this, the most powerful agent is *mercury*. But when we consider the variety of constitution in patients attacked with syphilitic iritis, the impaired state of general health they frequently exhibit, in consequence of venereal taint, and the period at which the iritis sometimes occurs—namely, while they are only just recovering from the debilitating effects of salivation—it is evident that, in a treatise like the present, little more can be done than to indicate the outlines of treatment, and that the judgment and tact of the surgeon must be brought to the careful study of each individual case.

¹ I cannot point out any really good representation of iritis in its early stage. Indeed, it is hardly possible for an artist to convey a true notion of the delicate changes in form and colour which characterise the disease at that period.

² This form of obstruction is sometimes called 'spurious cataract,' but the term is manifestly improper, as the word 'cataract' should be strictly limited to opacity of the lens itself.

When a recent case of syphilitic iritis comes before us in a patient of good general power, we may at once order two grains of calomel, with a third or half a grain of opium, to be taken night and morning; first clearing the bowels, if necessary, by a rapidly-acting aperient. In private practice, where our patients are not necessarily exposed to the weather, the calomel may be given more frequently, but in smaller doses; a grain, for instance, every four hours, combined with just enough opium to prevent purging. By some, small and frequently repeated doses of grey powder are preferred to calomel, whilst others give the preference to mercurial inunction. Calomel vapour baths have the advantage of bringing the patient very gently under the mercurial influence; they very rarely salivate, and do not disorder the digestion.

The effect of the mercury must be judged of by the state of the eye, not by the soreness of the gums. Indeed, I look upon soreness of the mouth as a condition to be always avoided, if possible; never to be willingly produced, as is so often the case. As soon, therefore, as the gums begin to be at all affected, the calomel is to be given less frequently; the absorption of the exudation in the pupil being the test of the mercury having been effectual. The two-grain pills may be taken once instead of twice a day; the grain every four hours changed to the same quantity every twelve hours, and then taken at twice that interval of time.

A patient sometimes comes before us with recent iritis, which has come on while he was actually under the influence of mercury, given for venereal disease. What are we to do in such a case? Perhaps we shall find that the patient, while taking the mercury, has been kept on very low diet, deprived of all animal food, and restricted to 'slops.' In that case, the mere change to a better diet—animal food and other nutriment being given, with a moderate quantity of the stimulant to which he has been accustomed—will often effect a surprising change, and stop the further effusion of lymph; while iodide of potassium, with bark, or, if the patient be extremely depressed by the mercury, even quinine alone, will at once cause absorption of the lymph to begin.

Or a directly opposite state of things may exist. The patient may have sought relief from the depressing effects of too much mercury by indulging in stimulants, and in this way may have induced an irritable condition of the circulation, quite incompatible with a due interchange of material in the system. Restriction of stimulants within due bounds will be as essential in this case as their use had been in the case of the ill-nourished and anæmic patient.

If a patient has been attacked with syphilitic iritis while under the depressing influence of too much mercury, given for general syphilis, and it has been found necessary to suspend the use of the mercury until tonics and a change of diet should have improved his general health, we shall often find, that by resuming the mercury in *small* doses, while at the same time we continue the tonics, the iritis will yield, although it may have resisted the large doses which had been given under circumstances of over-stimulation or deficient nutrition.

Turpentine was recommended by Carmichael, as a substitute for mercury, in those cases to which I have alluded as unsuitable for the administration of the latter on account of general debility. I have, however, found more benefit from the use of iodide of potassium, or even of very small doses of mercury, combined with tonics and improved diet, as above described. I have sometimes found turpentine of service in cases of rheumatic iritis, characterised by hyperæmia of the iris and sclerotic, but unattended with much disposition to effusion of lymph.

Whether the iritis be treated with mercury or not, the pupil is to be kept dilated by means of atropine.

Syphilitic iritis has often a tendency to become *chronic*; each relapse being characterised by a slight sclerotic zone, a yellowness of the aqueous fluid, giving a greenish tint to blue irides, general dimness of sight, and a slight filmy deposit in the area of the pupil. This chronic form is chiefly found in patients who are the subjects of tertiary syphilis. and a carefully-regulated course of iron often affords the best means of treatment.

In describing iritis, I have hitherto spoken only of those changes which are visible under ordinary observation; but the ophthalmoscope has demonstrated to us, what we formerly could only guess at, namely, that in iritis the deeper structures of the eye are often seriously affected.

To attempt to examine the fundus oculi during an acute attack of iritis, would be not only useless, but injurious; for the exudation deposited in the pupil, and perhaps in the vitreous humour also, would prevent any clear view of the parts behind; while the glare of light would be almost certain to increase the already existing hyperæmia of the organ. We often, however, have the opportunity of examining the fundus after all inflammation has passed away, leaving the cornea, lens, and vitreous humour transparent. We can then fully appreciate the close connection between syphilitic inflammation of the iris and of the choroid, and understand why it is, that in cases of so-called 'iritis,' the dimness of vision is often out of all proportion to the changes in and about the iris.

One of the sequelæ of iritis (I use the word 'iritis' in its more extended sense) is a cloudy condition of the vitreous humour, in which filaments and shreds, varying in shape and size, float freely in every direction. These bodies, although really whitish, of course appear black, or nearly so, when seen against the illuminated fundus oculi. They appear to be inflammatory deposits, intermixed in some instances with broken-up hyaloid membrane.

Large, irregular, white patches are scattered over the fundus, in some cases involving the greater part of its surface. Patches and dots of black pigment are frequently seen scattered over and among these opaque portions. (Plate I. fig. 3.)

Hence, it appears that syphilitic inflammation, when it attacks the eye, may exhibit its chief phenomena in the iris, involving the deep structures only to a very slight extent; or both may be equally affected; or lastly, the deep structures may suffer in such a degree as almost to become useless, while the iris shows little, if any, sign of inflammation, and the patient is hardly aware of the eye being the subject of disease, until vision is found to be almost lost.

SYPHILITIC IRITIS IN INFANTS.

Iritis is one of the rarest forms in which hereditary syphilis manifests itself during infancy. The careful researches of Mr. Hutchinson,¹ however, have shown that it is not quite so rare as has been supposed; and it probably often escapes notice on account, as he observes, of the very small amount of local symptoms which it causes, coupled with the fact that infants usually keep their eyes shut. During ten years I saw but five or six cases of syphilitic iritis in infants, among the many thousands of patients whom I treated at the Moorfields Hospital. Some of these infants presented the stunted and unhealthy aspect which usually accompanies inherited syphilis, but two, whose cases I have elsewhere reported in full,² were well-grown children.

One of the most striking peculiarities of iritis in infants is the very slight development of a sclerotic zone, that unfailing sign of iritis in the adult. Indeed, in some of the cases I have seen, sclerotic redness could hardly be said to exist.

The infant at the age of from two to ten months is attacked with copper-coloured eruption; perhaps also with mucous tubercles about the genitals, aphthæ in the mouth, and 'snuffles.' The eyelashes fall off, and sometimes the nails also are partially detached. In some cases the skin presents a peculiar dusky tint, and is wrinkled and scurfy.

The lymph does not assume the form of solid tubercular masses on the edge of the pupil, as in the adult, but either fills the area of the pupil, as a pale yellow semi-fluid mass, or sinks down to the bottom of the anterior chamber, like ordinary hypo-

¹ The result of Mr. Hutchinson's observations is given in *A Clinical Memoir on certain Diseases of the Eye and Ear, consequent on Inherited Syphilis, &c.*, 1863.

² *A Guide to the Practical Study of Diseases of the Eye*, 2nd edit. 1859, p. 149.

pyon. In one of the cases I saw, the lower half of the iris was completely hidden by a nodular mass of lymph, of a pale buff tint, which came into contact with the cornea, and completely filled the anterior chamber as high up as the middle of the pupil.¹ In another case, the effused lymph—for such it seemed to be—was scattered all over the lower half of the iris in the form of little, greyish-white, semi-transparent granules, like grains of coarse sand. The pupil was fringed with the same kind of deposit.

Treatment.—Before speaking of any special medicines for infants affected with syphilitic iritis, I would remark on the absolute necessity for their being suckled, and not brought up by hand. The milk of a healthy wet nurse would of course be infinitely preferable to that of an infected mother; but in the lower classes of society, among whom this disease is almost exclusively met with, the services of a wet-nurse can hardly be obtained.

Mercury should at once be given; and as hydr. c. cretâ is very uncertain in its chemical composition, I always make use of calomel, giving from a quarter of a grain to half a grain eight and morning. The effect of the medicine must be carefully watched from day to day, and as soon as the lymph begins to disappear from the eye, and the cutaneous eruption to fade, the dose may be gradually diminished; but it will often be necessary for the mercurial treatment to be continued, in a modified form, for several weeks. Weakly infants will be much benefited by taking five minims of Battley's liquor of cinchonæ twice a-day in a little milk. Provided the child sucks and digests well, the mercury does unmixed good, and, by counteracting the venereal poison, not only frees the skin from the specific eruption, but imparts to it a healthy hue, instead of the peculiar dusky colour which was originally so evident.

A few drops of a solution of atropine, containing two grains of the sulphate to an ounce of water, may be put into the eye once a day. So powerful a poison cannot safely be used without limit to young infants, even in its diluted form.

SCROFULOUS IRITIS.

Most of the patients in whom I have observed this form of iritis have been between five and fifteen years of age, and all have shown signs of a scrofulous constitution.

The iritis presented a resemblance to the syphilitic inflammation of adults, in respect of the abundant exudation which took place on the iris, and in the anterior chamber; but in the severer cases of the scrofulous form there was a still greater disposition to enlargement of the veins of the iris, and infiltration of its whole tissue, than is usually met with in syphilitic cases. In scrofulous iritis the large masses of yellow deposit are not so frequently limited to the margin of the pupil, but often appear midway between the pupil and the outer circle of the iris, or at the latter point, just in the angle between the iris and the cornea. Slight bleeding not unfrequently takes place into the anterior chamber, from giving way of the distended veins of the iris.

The cornea usually remains clear, but it sometimes presents a slight degree of mottled opacity, especially towards the lower part.

Treatment.—In the treatment of scrofulous iritis, as in all scrofulous affections, the diet and general mode of life deserve the utmost attention. Abundance—not excess—of animal food; warm clothing, pure air—sea-air, if attainable—are all important adjuncts to the medical treatment. Cod-liver oil is often of great service, and may be taken in combination with the other remedies. The bowels are usually irregular, and the appetite bad; and a mild aperient will be occasionally required; but care should be taken to avoid drastic purgatives, such as scammony and jalap.

When there is abundant inflammatory exudation into the anterior chamber, without much enlargement of the veins of the iris, or development of a sclerotic

¹ *A Guide to the Practical Study of Diseases of the Eye*, 2nd edit. 1850, p. 149, fig. a.

zone, half a grain or a grain of calomel at night, and two or three grains of quinine, or ten or twelve minims of liquor cinchonæ, taken an hour or so after a meal, will often produce a rapid absorption of the effused fluid. Where the exudation assumes the solid form, infiltrating a considerable portion of the iris, or appearing at its inner or outer circles as large yellow nodules, reddened with vessels, the iodide of iron is often useful, both in promoting the absorption of the deposit, and in diminishing the vascularity of the iris itself.

All stimulating lotions must be avoided; nor, indeed, except atropine, is any local application of service.

A form of iritis may be not very infrequently observed in youths and young adults, usually of a scrofulous diathesis, which differs from that just described by the little prominence of the characteristic iritic symptoms. Gummata are inconspicuous or absent, and a slight cloudiness of the pupil and a few small synechiæ, with a slight change in the colour and lustre of the iris, and sluggishness of the pupil, are the principal evidences of inflammation apparent in the iris itself. That which is eminently characteristic of this form of iritis is the occurrence on the back of the cornea of numerous opaque dots, most of them so minute as to require a magnifier for their distinct recognition. Of these the larger may be observed to change their position; they gravitate slowly towards that part of the cornea which happens to be most dependent. They are, therefore, probably fibrinous coagula. The smaller dots are fixed, and these have been shown, in some instances at least, to be patches of proliferating and degenerating epithelium.

This form of iritis is the *aquo-capsulitis* of the older surgeons, the serous iritis of modern continental authors. It is an insidious and usually very chronic disorder. Topically atropine, internally cod-liver oil, and ferric iodide, corrosive sublimate in small doses, and potassic iodide, will be found the most useful remedies.

GONORRHOEAL AND ARTHRITIC IRITIS.

I have never been able to trace an attack of iritis as a result of simple gonorrhœa; although, of course, it may often happen that a patient is attacked with ordinary rheumatic iritis within a short period of his having had urethral discharge. Gonorrhœa is unfortunately so common, that were there any definite form of iritis dependent upon it, so marked a sequel of the discharge would be constantly brought under our notice.

Neither have I seen cases of iritis which I could refer to gout. The descriptions of 'arthritic iritis' one meets with in books are chiefly taken from German writers, especially Beer and his contemporaries, whose account of the disease, which they term *gouty* inflammation, more nearly answers to that of chronic glaucoma. The ash-coloured ring in the sclerotic, immediately surrounding the cornea, described by German writers as the *arthritic* ring or circle, and regarded by them as diagnostic of arthritic iritis, is not peculiar to any special form of inflammation. Its presence merely depends upon the anatomical arrangement of the adjacent portions of the sclerotic and cornea. When these two structures are united obliquely, so that a considerable extent of the sclerotic is overlapped by the cornea, the vessels of the former do not appear to advance so near to the iris as in other cases; and hence a narrow ring, of a paler tint, is interposed between the iris and the dense plexus of vessels forming the sclerotic zone.

[That, exceptionally, iritis is actually a sequel of gonorrhœa, such cases as the following afford very strong presumption. A gentleman in a public office, æt. 24, in sound health, caught a clap. He had never had rheumatism, and his family, several members of which were well known to me, appeared remarkably free from any gouty and rheumatic tendency. The local symptoms of the gonorrhœa were very acute. About the end of the second week he was attacked with synovitis in both knees and ankles, which proved very intractable, and left these joints weak and stiff long after the inflammatory symptoms had disappeared. Within a very

DISEASES OF THE EYE.

few days of the accession of the synovitis, iritis developed itself in both eyes. The symptoms were very acute: the gummata in the iris were very large and conspicuous, the congestion was considerable, and the pain in and around the eyeball was severe. In spite of an energetic treatment, the iritis proved very obstinate; it subsided slowly and left large synechia. Nearly four years later he again acquired gonorrhœa, which was very quickly followed by another attack of synovitis in the same joints, and very slowly after the accession of this he again had a double iritis, the symptoms and course of which resembled those of the first attack. In the interval his health had been good, and he had remained free from joint and eye inflammation. There was not the slightest ground to suspect syphilis. I have seen several similar cases, in most of which there was also gonorrhœal rheumatism, but in some this joint complication was absent. In all the gummata in the iris and the congestion were considerable.—J. W. H.]

USE OF ATROPINE IN IRITIS.

In a former edition of this work I spoke unfavourably of the employment of atropine during the acute stage of iritis. Subsequent experience has led me to modify my opinion on this subject. Of course the action of atropine will be most evident in those cases where the inflammation is quite recent, and where consequently the tissue of the iris is not, as yet, much thickened by congestion of its vessels, nor infiltrated with lymph. Where abundant effusion of the latter has taken place around the margin, and within the area of the pupil, atropine may not produce any change visible to the observer; but when this stage of effusion has not yet arrived, or when, at a later period, it is passing off, persistent dilatation of the pupil may be induced by atropine, and such dilatation will have the effect of hindering the formation of adhesions between the iris and the capsule, or of causing such adhesions, if already existing, to give way. In all cases of iritis, therefore, a solution of atropine should be dropped upon the eye night and morning. Where the inflammation is recent, and atropine is used in anticipation of lymphatic effusion, rather than to counteract the solidification of deposits already formed, a solution of two grains of the sulphate of atropia, in an ounce of distilled water, may be employed; but in the more acute cases a solution of double that strength will be required.

Not contented with insisting on the utility of atropine as an adjunct to mercury in the treatment of iritis, some recent writers have even gone so far as to recommend that the disease should be treated by the use of atropine alone. More dangerous trifling I cannot conceive. No doubt cases of iritis occur in which the tendency to effusion of lymph can hardly be said to exist at all, and such exceptional cases may possibly get well without any mercury being given. But we are not warranted in assuming that a case of iritis which begins in a mild form is going to maintain that character throughout, and it is our duty to employ that agent which above all others has the property of counteracting the effusion of lymph, and the consequent loss of transparency in parts essential to vision. And what rational cause is there for this anxiety to avoid the employment of mercury? Used ignorantly, as we too often see it used, mercury is a fearful curse to mankind; but, moderately and judiciously used, it is one of our greatest blessings. If patients with iritis are to be so impregnated with mercury that profuse salivation and all the other miseries of mercurial poisoning are induced, they may well pause before submitting to a remedy almost as bad as their disease. But this kind of mercurial treatment is never necessary. Those cases of iritis commonly do best where the mouth has not even been made tender, and therefore there is no real necessity for the attempts that are being constantly made to treat iritis without mercury. We are often told that iritis will get well without it—and so no doubt it will, in a certain sense, get well without any treatment at all. But the eye is in one respect a wholly exceptional organ. Once let its transparent tissues become opaque, and then, although the eye may in a certain sense have recovered from an inflammatory attack, the function of the organ is impaired or destroyed. The treatment of iritis consists in speedily prevent-

ing the formation of patches or films of inflammatory deposit in the transparent media of the eye, and if mercury has the invaluable property of doing this, it seems criminal in the surgeon to neglect the use of it.¹

It is a curious fact that in certain persons the application of sulphate of atropia to the conjunctiva will set up all the symptoms of acute catarrhal ophthalmia complicated exceptionally by acute eczema of the eyelids and cheek. I do not speak of solutions to which a few drops of acid or of alcohol have been added. Such additions, I know, are sometimes made; but they are as unnecessary as they are irritating, for well-made sulphate of atropia is quite soluble in distilled water. The first instance of my meeting with this effect of atropine occurred in a hospital in-patient who used drops from the same solution that was being dispensed at the time to many hundreds of others, none of whom experienced any similar inconvenience. As soon as the drops were discontinued, the conjunctival inflammation rapidly subsided, and it was again excited by a reapplication of the atropine. I have since met with another case, in which great irritation, both of the eye and eyelids, followed the use of drops which I myself applied and knew to be perfectly neutral. In such cases sulphate of duboisia may be advantageously substituted for atropine.

SEQUELÆ OF IRITIS.

Besides the changes already mentioned as resulting from iritis, such as obstruction, or closure of the pupil, the inflammation is sometimes followed by degeneration of structure, which more or less involves the whole tissue of the iris.

Chronic iritis, for instance, in a cachectic subject, especially if the disease has been allowed to run on unchecked, is apt to induce a permanent thickening of the iris, all appearance of its normal fibrous tissue being lost, and the veins of the part becoming enlarged and irregularly dilated.

On the other hand, the constant pressure of a calcified lens, which has become thrust forward against the iris, will sometimes induce such wasting of its tissue, that the uvea wholly disappears, and the thin web of iris which remains allows the chalky-white lens to be distinctly seen through it.

Another consequence of iritis is the distension of the iris into *pouches*, which are formed in the following way. An attack of syphilitic iritis, left to itself, or badly treated, causes the whole margin of the iris to adhere to the capsule of the lens; the pupillary area being, at the same time, very small, and filled up with opaque deposit. All communication between the anterior and the posterior aqueous chamber is cut off; and the aqueous fluid secreted in the latter cavity, not being able to pass through the pupil into the anterior chamber, accumulates behind the iris, and gradually distends and presses it forwards; the pupillary margin meantime being prevented from advancing with the rest of the iris in consequence of its union with the capsule.

If the uveal surface, except just at the edge of the pupil, be free from adhesion, the whole anterior surface of the iris forms one convex mass, with a deep depression at its centre, in the position of the closed pupil; but if the uvea be here and there adherent to the capsule of the lens, the iris at those spots remains retracted, like the pupil, while intervening portions of iris are thrown into a series of pouches which may almost, or quite, touch the cornea. These pouched portions of iris lose their fibrous appearance, and have a dark slaty tint.

Vision, in such cases, is reduced to mere perception of light; but, provided the retina be sound, excellent sight can often be restored by means of a carefully-planned and skilfully-executed artificial pupil.

In cases of long-continued iritis, combined with disease of the choroid, and of the anterior portion of the sclerotic, the iris not only becomes united to the capsule, and bulges forwards in the manner just described, but the fluid secreted in the

¹ Remarks on the use of atropine in iritis almost identical with the above were to have been added to the third edition of my *Guide to the Study of Diseases of the Eye*, 1866, but by inadvertence they were not sent to the printer.

posterior aqueous chamber, continuing to accumulate, exerts pressure on the anterior portion of the sclerotic, and stretches its weakened tissue. This gradually yields, and forms a *staphyloma scleroticæ*, a tense bluish-black prominence, streaked with the widely-separated whitish lines of the sclerotic fibres. At first, while the prominence is small, it is usually situated at the upper part of the globe, just behind the cornea; but the distension may go on until the whole of the sclerotic, between the line of insertion of the recti muscles and the margin of the cornea, forms one bulging lead-coloured swelling. *Staphyloma scleroticæ* is always a sign of the deeper tissues of the eye having suffered from disease, and, if developed to any considerable extent, would contra-indicate operations for artificial pupil or cataract.

Cysts of the iris.—In very rare cases a punctured wound of the iris, near its ciliary attachment, has been followed by a cyst-like expansion of its substance, in consequence, apparently, of the fluid of the posterior aqueous chamber finding its way between the uvea and the fibrous tissue of the iris.

These cysts present a dark slaty tint, which nearly approaches to black when their walls become very thin. The treatment of these cases is often extremely troublesome, on account of the readiness with which the expanded iris-tissue reunites after being lacerated. When the lens is *in situ*, and transparent, the difficulty is greatly increased.¹

[Cysts in the iris are of two kinds: (a) Watery cysts, hygromata, consisting of an extremely delicate membrane lined by a single layer of pavement epithelium; (b) Thicker walled cysts enclosing an opaque mass of scaly epithelium and epithelial debris. The close similarity of their contents to those of ordinary subcutaneous sebaceous wens places this kind of iritic cyst in the same category with these.

Both kinds of iritic cyst are in the great majority of instances of traumatic origin. Most probably originate in the iris, but some seem to originate in the ciliary region, and from this to invade the iris. Thorough excision of the cyst, including the iris with which it is connected, can alone be recommended. If any part be left behind, experience shows that the cyst soon forms again. Mere laceration, however free, is quite useless to procure a permanent result.—J. W. H.]

OPERATIONS ON THE IRIS FOR ARTIFICIAL PUPIL.

Many of the diseases and injuries affecting the iris and cornea described in the foregoing chapters, produce complete closure of the pupil, while others either cause it to become displaced from its natural position, or leave it more or less completely hidden behind a dense corneal opacity.

All operations for the relief of such obstructions or mal-positions of the pupil may be suitably described in this place; while the operation on the iris, for the cure of *glaucoma*, must be deferred until that disease has been considered.

The term *Artificial Pupil* must be understood to include not only the formation of a new aperture in the iris, when the portion forming the natural pupil has prolapsed through a breach in the cornea, but also the reopening or the enlargement of the natural pupil when obstructed by inflammatory deposit; or the displacement, towards a transparent part of the cornea, of a pupil which has become overshadowed and hidden behind a dense corneal opacity.

Before attempting any form of operation for artificial pupil, the surgeon must make himself thoroughly acquainted with the history of the case, and especially ascertain for himself the following conditions:

First, whether the eye perceives light. Mere obliteration of pupil will not deprive the eye of this power, provided the retina be sound; for we know, by personal experiment, that even the thickness of our closed lids does not prevent our noticing the shadow of a hand passing between our eye and the window.

¹ See a case reported at length in my *Guide to the Study of Diseases of the Eye*, 2nd edit: 1859, p. 408.

Secondly, the presence or absence of the lens must, as far as possible, be ascertained, and, if present, whether it is transparent or opaque.

Thirdly, the cornea must be carefully examined, as to its degree of transparency.

Fourthly, the state of the iris itself must be noticed. The existence of chronic iritis would induce the surgeon to defer the operation until the inflammation had ceased. A thickened iris, in which all trace of its peculiar fibrous structure is lost, is specially unfitted for an operation, as it breaks away under the slightest traction, and, if cut, the wound does not gape, so as to form a permanent aperture.

As a rule, it is not desirable to operate for artificial pupil when the other eye is perfect.

The principle, not to inflict unnecessary injury on the parts operated upon, which holds good of every surgical operation, applies with peculiar force to that for an artificial pupil; for often the portion of transparent cornea is very small, and a needlessly large cicatrix may seriously diminish the patient's field of vision.

Generally speaking, a small artificial pupil is more useful than a large one; that is to say, if it can be made in such a position that all the cornea in front of it is transparent. Sometimes, however, the pupil has to be drawn from behind an opaque corneal cicatrix; and in that case it is only by making a large aperture that a sufficient portion of it can be rendered available.

Inasmuch as the natural pupil is placed nearly in the centre of the iris, it would follow that a similar position must be the most suitable for an artificial aperture. Various considerations, however, may induce the surgeon to select a more peripheral situation; but he should always strive to approach the centre of the iris, as far as circumstances will allow.

Peculiar care is required in the examination of those cases, frequently brought under our notice, in which the greater part of the cornea appears converted into a more or less prominent, densely opaque, white cicatrix, after severe purulent or gonorrhœal ophthalmia. The patient may have good perception of light, and there may be an appearance of a narrow strip of semi-transparent cornea adjacent to the sclerotic, suggesting the possibility of an artificial pupil being made. And yet the appearance of true corneal tissue may be altogether deceptive.

When the whole cornea has been destroyed by ulceration, as in severe purulent ophthalmia of infants, or the gonorrhœal ophthalmia of adults, the iris is for a time laid bare; but very soon exudation takes place on its surface, while the iris, yielding to the pressure behind, gradually forms the prominence known as *staphyloma*. The greater part of this fibrinous coating of the iris eventually becomes white and opaque, and traversed by ramifying vessels; but the marginal portion of the iris is covered by a semi-transparent tissue, united, perhaps, to a very narrow ring of true cornea, just that portion immediately connected with the sclerotic. No space, however, exists between this semi-transparent, cornea-like tissue, and the fibres of the iris; and any attempt, therefore, to make an artificial pupil in this situation would only end in disappointment.

The different modes of making an artificial pupil may be classed under four heads: *laceration, incision, excision, and ligature*.

1. *Laceration*.—This consists in tearing away a certain portion of the iris from its ciliary attachment. It is scarcely applicable to other cases than where there is only a very limited marginal portion of transparent cornea, the rest being opaque. Here, with a slender forceps introduced through an incision in the opaque part of the cornea, the iris corresponding to the transparent part may be seized, torn from its peripheral attachment, and cut off.

2. *Incision*.—This is the oldest form of operation for artificial pupil, being that employed by Cheselden in a case commonly spoken of as the first in which an artificial pupil was made. The operation is founded on the elasticity of the fibres of the iris, which causes them to retract when cut across, so as to leave an aperture for the transmission of light to the retina. Hence it will be seen that the operation is likely to succeed in proportion to the state of tension and retractile power of the iris, and will be inadmissible in those cases of closure of the pupil resulting from chronic iritis,

or any other disease of the iris which has caused softening and degeneration of its tissue. The operation by incision would also be contra-indicated if the lens were present, as injury to it must almost inevitably follow the penetration of the iris by a cutting instrument.

The operation, therefore, is much restricted in its application, and is almost confined to those cases in which, after extraction of a cataract, there has been prolapsus iridis to such an extent as wholly to obliterate the pupil, the fibres of the iris remaining on the stretch in consequence of so large a portion becoming healed into, and confounded with the corneal cicatrix.

The incision is made either with a cutting-needle or a fine narrow knife, or else with scissors. The needle or knife is passed into the anterior chamber close to the edge of the cornea, and when the point has been carried a little beyond the middle of the iris, the cutting edge is turned backwards, the point is made to penetrate the iris, and its fibres are divided to such an extent as may be desired. The needle or knife is then rotated into its original position and withdrawn.

Maunoir¹ modified the operation by using scissors for dividing the iris, but of course they required a large corneal wound for their introduction, and neither the linear nor the V-shaped incision which he recommended was found by any means easy to accomplish when the iris had become flaccid after the escape of all the aqueous humour. If scissors are employed at all, the cannula-scissors invented by Wilde would be found far more convenient for incising the iris, as they may be so constructed as to cut their own way into the cornea, and fill up the wound they make, thus retaining a good deal of the aqueous humour. They are now nearly superseded by the forceps-scissors of Weiss.

In cases where a very narrow strip of cornea alone remains transparent, after sloughing or ulceration throughout the rest of its extent, it becomes of the utmost importance to accomplish the division of the iris with as little injury to the cornea as possible. In such cases I have found the most useful instrument to be a broad needle, cutting on both sides for a short distance from its point.

3. *Excision*.—In cases where the pupil had become drawn together, and its contracted area blocked up with an opaque membrane, in consequence of iritis, the lens being unaffected, the operation of incision, either by the knife or scissors, was contra-indicated, since it was hardly possible to puncture the iris with a cutting instrument without wounding the lens. The operation of excision therefore became necessary, which was performed as follows: an opening of sufficient size having been made in the cornea, a forceps was introduced into the anterior chamber, its branches were then opened, a portion of iris was included between them, and, being grasped, was drawn out of the corneal wound, and cut off with scissors. The objection to this operation was the difficulty of limiting the quantity of iris removed; the pupil was usually very large, and extended almost, if not quite, up to the border of the cornea.

The 'blunt hook,' invented by Tyrrell, introduced a more delicate and precise mode of operating; and, for special cases, has not been superseded by any subsequent contrivance. It requires only a very small corneal wound for its introduction; and it can be employed without risk in cases where the lens is *in situ* and transparent.

It is specially adapted for the following cases. First, when, after extraction, there has been extensive prolapse of the iris, so as to obliterate all but a very small vestige of the pupil. Secondly, when, in consequence of iritis, the whole pupillary margin has become adherent to the capsule, the peripheral portion of the lens itself remaining transparent. And, lastly, when the iris is perfectly healthy, but the pupil is hidden behind a dense central opacity of the cornea, the rest of the cornea remaining clear.

a. In a case such as I have alluded to under the first head, we will assume the lens to have been extracted through an upward section of the cornea. The artificial enlargement of the pupil would be made in the following manner: the lids being held apart with a spring-wire speculum, the surgeon steadies the globe by nipping

¹ *Mémoires sur l'Organisation de l'Iris et l'Opération de la Pupille artificielle*, Paris, 1812.

up with a forceps a little fold of the ocular conjunctiva, just above the upper edge of the cornea; he holds in the other hand the broad cutting-needle, which he passes through the lower edge of the cornea, close to its junction with the sclerotic. If the width of the blade be properly proportioned to the size of the hook, a simple puncture will suffice; but if the needle be narrow, its edges may be used to enlarge the wound to a sufficient extent. The needle should now be gently withdrawn; not with a jerk, as such a movement is usually followed by a spurt of aqueous humour, and it is important to retain as much of that fluid as possible. The surgeon then takes the blunt hook, and passes it in through the corneal wound, the flat side of the hook coming in contact with the iris. The instrument, held in this position, is rapidly passed upwards, until its extremity reaches the small pupillary opening; then the handle is rotated so as to allow of the lower edge of the displaced pupil being firmly caught in the bend of the hook; gentle traction is then made, and at the same time the handle is again rotated in such a manner that the short, bent portion faces directly forwards. It is only in this position that the hook can be withdrawn through the corneal wound without catching in it; and it is for the want of attending to this little manœuvre that those who use the blunt hook so frequently find a difficulty in withdrawing it. When the hook, holding the iris, has been fairly brought out of the wound, an assistant, with a pair of fine scissors, snips through the iris, close to the hook, if a good portion of iris has been secured; but should the iris have torn, and only a small portion been withdrawn, it may be desirable to cut through it close to the cornea. Sometimes the tissue of the iris is so much softened that it breaks in coming out, and then the surgeon must use a fine forceps to catch what remains, and so prevent its retracting into the anterior chamber.

Any little shreds of iris that hang in the wound should be returned by means of a little spatula, so that the lips of the wound may come into exact apposition.

The description just given of the mode of using the blunt hook, and of other details in the operation for artificial pupil, will apply to the different modifications subsequently described. The wire speculum, and forceps to steady the globe, will always be found useful, often indispensable. The patient should lie down on a couch; and the best light is usually obtained by the foot of the couch being turned towards the window; the surgeon standing or sitting behind the patient's head. The use of chloroform will be regulated by circumstances; it is commonly necessary with children, or very intractable patients, but the pain of the operation, when skillfully performed, is so trifling, that patients possessed of self-control can usually dispense with chloroform altogether.

b. The next class of cases in which the blunt hook should be employed is that where iritis has terminated in adhesion between the whole or the greater part of the pupillary margin and the capsule of the lens.

At p. 63, under the head of *Sequelæ of Iritis*, I have described such a condition of closed pupil, accompanied by a bulging forward of the iris, in consequence of the pressure of the fluid secreted in the posterior chamber of the aqueous humour. When the whole surface of the uvea has become adherent to the capsule of the lens, these pouch-like dilatations of the iris do not exist. When only the extreme edge of the pupil adheres, the rest of the uveal surface remaining free, the contracted pupillary area, blocked up with opaque membrane, remains fixed, while the iris bulges all round it, so as in some places to touch the cornea. Partial adhesions of the uvea to the capsule give rise to deep grooves, subdividing the iris into separate pouches; the accumulation of fluid behind the iris being unable at these points to thrust it forwards.

When the whole cornea is clear, and the surgeon can select the position in which to make an artificial pupil, he will find it best to extend it either directly outwards, or directly downwards; and in a case of pouched iris, such as I am now considering, if a depression in the iris exists in either of these directions, he may take advantage of the circumstance to insinuate the cutting-needle and hook between the cornea and iris, without risk of wounding the latter.

When, however, he has succeeded in catching the edge of the pupil, and drawing

out a piece of iris, he may perhaps be disappointed to find that he has removed only its fibrous portion, and that the aperture he has still made is blocked up by a layer of uveal pigment, adherent to the anterior capsule. Although in such a case the first operation may have done but little toward restoring sight to the patient, it will be found to have greatly facilitated a second operation, as the fluid which had been pent up in the posterior aqueous chamber can now find its way into the anterior chamber, and, in consequence, the whole iris will lose its pouched appearance, and recede from the cornea. When the slight irritation caused by the first operation has passed, the cutting-needle may be introduced at a new point of the cornea, the edge of the artificial pupil caught with the blunt hook, and drawn in such a direction as to remove a portion of iris which had never been adherent to the capsule. If the periphery of the lens be transparent, this second operation will at once open a way for the rays of light to pass to the retina.

c. *Extensive ulceration* at the centre of the cornea, stopping short of actual perforation, may form a cicatrix so large and opaque as entirely to cover the pupil, restricting the patient's sight to the perception of large objects placed very much out of the line of direct vision. The iris itself, when viewed through the transparent periphery of the cornea, may present a perfectly healthy appearance, and there may be every reason to suppose that the whole globe, with the exception of the cornea, has been unaffected by disease. In such a case, the object of the surgeon will be to displace the pupil either outwards or downwards, accordingly as he finds the outer or the lower portion of the cornea preferable in respect of transparency. The blunt hook is the most convenient instrument for effecting this displacement, as it does not endanger the lens, which I am supposing to be perfectly healthy. An opening having been made, either at the outer or lower margin of the cornea, in the manner described at p. 67, the free margin of the pupil is to be caught with the hook and drawn out, a larger or smaller piece of iris being cut off according to the size of the corneal opacity beyond which the pupil is to extend.

4. *Ligature*.—In spite of every precaution, it is not always possible to limit the size of the pupil, which sometimes opens out to an extent greater than was originally intended. To remedy this inconvenience, Critchett suggested an operation which he termed 'Iridesis,'¹ and which is applicable to a limited number of other cases of artificial pupil besides that just described; as, for instance, where prolapsus iridis has occurred, and so much of the pupillary margin has been drawn into the cicatrix as to reduce the area of the pupil to a very minute aperture: or where the whole pupil has been displaced towards the extreme edge of the cornea, and there overshadowed by an opacity. A puncture is made through the cornea sufficient for the introduction of a cannula-forceps; a small portion of the iris near its ciliary attachment is grasped, drawn out through the wound, and tied there with a very fine silken thread. This transforms the pupil into an elongated slit. Should this aperture be found insufficient, it may afterwards be enlarged by tying a second portion of the iris in such a position as to draw the pupil into a triangular form.

The operation by *ligature* has the advantage of leaving the margin of the pupil uninjured; and in some cases it has been found that even a certain amount of dilatation and contraction of the aperture has been maintained. It is not now often practised.

It is far from my intention, in treating of ophthalmic surgery, to attempt a record of all the schemes that have been suggested or put in practice. To describe the operations and instruments which artificial pupil alone has called forth would be to enumerate a long and tedious catalogue of inventions, most of which have been long since abandoned as useless.

After-treatment of an artificial pupil.—The various forms of operation I have recommended in the foregoing pages, if skilfully performed, inflict so little injury on the eye, that, provided the parts be in a fit state to undergo the operation—all

¹ *Iridesis* or *Iridodesis* would be a more correct word to imply tying (*deusis*) of the iris, inasmuch as the genitive of *iris* is *iporis* or *ipidoris*.

inflammation being extinct, and the patient's general health having been properly attended to—little more than repose of the eye is required to enable the cornea to heal; and when that is effected, the wounded iris soon regains its natural texture and appearance. We are often, however, obliged to operate on an iris which has undergone long-continued and repeated attacks of inflammation. The tissue of such an iris is soft and spongy, and its enlarged vessels, when torn or cut, pour out their blood into the anterior chamber, where it may remain for many weeks, or even months, without being absorbed. On the contrary, when the iris is sound, and the patient's health good, but little blood is effused into the anterior chamber, and that little commonly undergoes absorption in the course of a few days.

After an operation for artificial pupil, *both* eyes should be lightly bandaged, or the lids closed with strips of plaster. On the second or third day the eye may be examined. Should there be much sclerotic redness, or intolerance of light, the operated eye must be again closed for a day or two. In most cases, at the end of a week from the operation, a large eyeshade will be sufficient; but the patient must be warned against too soon exposing the eye to strong light; and if the case be one in which the patient has for several years been limited to perception of light, he must be forbidden to strain his newly-regained powers of sight by premature examination of small objects. A pair of tinted glasses should be worn for some time after he has begun to go out of doors.

If the operation has been performed under chloroform, it may not be advisable to give any opiate or narcotic at night; but in excitable patients, who have not taken chloroform, it is sometimes necessary to give some mild narcotic. From twenty-five or thirty minims to a drachm of tinct. hyoscyami, in camphor-mixture, is what I usually order as a night-draught for an adult who has not been habitually addicted to the use of opiates. But many patients do not require anything of the kind. There is no reason for denying the patient a moderate quantity of plain animal food on the day of the operation, as well as on the following days. Nor should stimulants be wholly forbidden to those who are accustomed to their daily use. I need hardly say that a patient who is to spend the first day after the operation in bed, and perhaps the rest of the week in the house, is not to live as freely, and have the same amount of stimulants, as if he were taking daily exercise, and were engaged in active pursuits. But, on the other hand, it is absurd to keep a patient on low diet, and deprived of all accustomed stimulants, because a small puncture has been made in his cornea, and a little bit of his iris removed. Old and feeble persons cannot bear such reduction; and if any considerable quantity of blood has escaped into the anterior chamber, the best way to hasten its absorption is to keep the patient's powers up to a healthy standard, by plain nutritious diet, and just such an amount of stimulants as will maintain the circulation at a proper point of vigour.

CHAPTER VII.

DISORDERS OF THE CHOROID, RETINA, AND OPTIC NERVE.

THE genetic association of the hexagonal pigmented epithelium of the choroid with the retina, the nourishment of the bacillary layer of the latter by the chorio-capillaris, and the frequent and ready extension to the retina of morbid processes beginning in the choroid, induce us to treat of the diseases of these coats in one chapter.

Coloboma.—Whilst describing coloboma iridis, reference was made to the backward extension of the cleft through the deeper structures in some instances concurrent with it. This defect is due to imperfect closure of the cleft which grooves the lower half of the embryonic eyeball, and discovers itself ophthalmoscopically by a white oval or pear-shaped figure stretching from before backwards along the lowest part of the fundus oculi. In extreme examples the narrow, tapering end of this

figure is traceable nearly or quite up to the fissure in the iris, whilst the larger rounded end includes the optic papilla. In such cases the upper half of the sclero-choroidal foramen is normal, but the lower half appears absent; there the papilla seems to an inexperienced observer to merge without definite limit into the white figure of the coloboma. It is, however, always distinguishable from this by its pinkish-grey colour, and its less bright reflex. In such extreme examples of coloboma the branches of the central vessels distributed to the upper half of the retina are usually larger and more conspicuous than those supplied to the lower half. Where the coloboma is of less extent and it does not include the sheath of the optic nerve, the larger end of the white figure is separated from the papilla by a band of normal choroid.

The area of the coloboma is formed by a connective-tissue membrane intercalated between the edges of the sclerotic defect, which often lies in a slightly deeper plane than the parts around, as if bulged slightly outwards. An excess of pigment in the choroid along the margins of the white figure intensifies their distinctness. The retina in some instances appears to span the hinder part of the coloboma, and in others to be applied to the intercalated connective-tissue membrane. That it is structurally defective is shown by a corresponding defect in the visual field.

DISEASES OF THE CHOROID.

1. *Hyperæmia*.—Ophthalmoscopically, congestion of the choroid is inferred from increased redness, dilatation, and varicosity of the larger blood-vessels, particularly of the veins. The deeper redness is the collective effect of turgescence of the choroidal capillaries, which even when swollen are not recognisable individually. In estimating it regard should be had to the quantity of pigment present in the choroid, the appearances noted in one eye should be controlled by those observed in the other; and the natural differences of size and arrangement of the veins in different regions of this coat should ever be kept in mind. The vascular system of the choroid has three areas between which there is less free intercommunication than between the vessels within each area. There are a posterior area chiefly fed by the posterior ciliary arteries, an anterior area to which the short anterior ciliary arteries are distributed, and the area which includes the *venæ vorticosæ* with their tributaries. Where the choroid is deeply pigmented, the condition of the vascular system will be masked or even completely hidden.

2. *Choroiditis*.—Inflammatory exudations infiltrate and swell the stroma, or distend the looser tissue which connects the choroid with the sclerotic, or are poured out upon the inner surface of this coat between it and the retina.

The presence of exudation destroys the natural transparency of the choroidal tissues, and thus masks the sharpness of their ophthalmoscopic image. It is not always easy or even possible to ascertain with perfect certainty the precise seat of a slight exudation. Where the transparency of the retina is preserved and the vessels of this coat are distinctly traceable across the opaque patch, the exudation is behind them in the outer layers of the retina, or upon or within the choroid.

Frequently a past choroiditis leaves indelible traces: white spots, the inner surface of the sclerotic exposed to view by the disappearance of pigment and atrophy of the choroidal tissues, stamp the former foci of inflammation, whilst brown or black fringing borders due to excessive formation of pigment indicate the zone of hyperæmia. (Plate I. fig. 3.)

DISEASES OF THE OPTIC NERVE AND RETINA.

Slight variations in the contour-figure of the optic papilla so frequently coexist with perfect functional integrity, that they should not be hastily looked upon as evidence of disease: they may be merely a congenital peculiarity, or an illusion due to a somewhat high degree of astigmatism.

Morbid changes in the form of the surface of the papilla are of two kinds, depression and elevation. The inexperienced observer should not mistake for a

morbid depression the slight central hollow, known as the physiological pit. Its extent and precise figure vary within small limits which are fixed by the arrangement of the outer layers of the retina at the sclero-choroidal foramen.

Depression.—Morbid depression is partial or general, and may be due to atrophic wasting alone, or to pressure followed by atrophy. Where due to atrophic waste alone; the surface of the papilla declines gradually from the periphery towards the middle, and it takes the form of a shallow, shelving saucer; and where produced by pressure and atrophy, the depression is abrupt, assuming the shape of a cup, and it may even undermine the margin of the sclero-choroidal foramen. (Plate II. fig 3.)

Ophthalmoscopic signs of depression of the surface of the papilla are (1) the altered direction of its blood-vessels, which are bent out of their natural course; (2) the unnatural distinctness of the details of the lamina cribrosa beyond the normal limits of the physiological pit; (3) a certain distribution of light and shade when the papilla is illuminated; and (4) the increased parallax of the images of objects lying over the margin of the sclero-choroidal ring above that of the images of structures lying near the middle of the papilla and not far from the inner surface of the lamina cribrosa.

Where the depression is slight and the slope gradual, the direction of the smallest visible vessels is a better guide than that of the larger vessels, because the smaller vessels on account of their minuteness are only apparent when they follow closely the surface of the papilla. Where the hollow is deep and abrupt, reaching or undermining the edge of the sclero-choroidal foramen, the change in direction here of the large branches of the vena centralis is very significant. Those portions of the veins which lie in the papilla appear to be angularly bent; and where the hollow is very deep and its sides steep and overhanging, the apparent lateral deflection of the veins is so great, that the continuity of these vessels with their continuations in the retina seems to be interrupted.

Elevation of the surface of the optic papilla, of slight extent and partial, is present where as a congenital defect the nerve fibres retain their white substance which augments their bulk. Such elevation is usually partial, affecting some segments of the papilla only. The white nerve-fibres may extend some distance into the retina in the form of white, radiating bands which may be distinguished from exudation by their brush-like feathered borders. But the common causes of elevation are congestive and inflammatory swelling. In estimating the value of redness of the papilla as an index of capillary congestion, the influence of contrast between the colour of the papilla and that of the fundus oculi around it must be kept in mind; and in judging of the import of an apparent turgescence of the vena centralis, the observer should take into account the refraction of the eye, because in the indirect method of ophthalmoscopic examination, the same collecting lens being used, where hypermetropia is present vessels of the same actual diameter appear larger, and in myopia they appear smaller, than in emmetropia.

CONGESTIVE SWELLING OF THE OPTIC PAPILLA.

(*Neuritis; Neuro-retinitis.*)

Congestive swelling of the optic nerve is ophthalmoscopically indicated by undue redness; by loss of transparency due to cedema which dulls the sharpness of the images of the lamina cribrosa, the margin of the sclero-choroidal foramen, and those portions of the vasa centralia which lie at some depth beneath the inner surface of the papilla; and by turgor of the veins which betrays itself, not solely by their unnaturally large calibre, but by arched direction in the papilla, and their tortuous course in the retina indicative of their elongation. In order to sharply see the summit of the swollen papilla and the surface of the surrounding retina, the observer is under the necessity of varying his accommodation, which proves that they lie in different levels.

The distinction between congestive and inflammatory swelling of the papilla is not always easy to make, for these conditions are not always sharply defined; indeed, one often merges insensibly into the other. In neuritis there is greater opacity, due

to exudation amongst its tissues, imparting to the papilla a dull grey colour, in some instances tinged with a rusty stain, caused by extreme capillary engorgement and minute hemorrhages. The arteries are more or less obscured; and the veins, always more conspicuous than the arteries, in consequence of their larger calibre and the greater tenuity of their walls which allows the purple blood-colour within them to be better seen, are visible only in those parts of their course which lie close beneath the inner surface of the papilla. The borders of the sclero-choroidal foramen are concealed, and peripherally the optic nerve passes without definite limit into the surrounding retina. The opacity not infrequently extends for some distance into the retina, particularly along the course of the larger blood-vessels. A faint radial striation is often apparent in the circumferential part of the papilla and adjoining retina.

Congestive swelling and neuritis may end in resolution and perfect recovery of sight, but too often they terminate in atrophy and blindness. The last is especially true of neuritis, after which the swelling of the papilla lessens, its opacity clears up, it acquires a pale greyish or bluish-white colour, it has a bloodless appearance, the turgescence of its large vessels is replaced by unnatural decrease of calibre, whilst their tortuosity persists, and its margin is frayed, blurred, ragged. A fact long recognised by ophthalmic surgeons, and particularly insisted on by Dr Hughlings Jackson, cannot be too widely known, viz. that congestive swelling and neuritis are not infrequently in their early phase compatible with good sight. Usually, however, before long visual acuteness suffers and the field becomes contracted. Congestive swelling and neuritis are both frequent concomitants of disease behind the eyeball within the skull. They may be occasioned by extension of inflammation forwards along the post-ocular part of the nerve to that within the eyeball, and by any circumstances which unduly raise intracranial pressure. It is the frequent relation of congestive swelling and neuritis to intracranial disease which makes the prognosis so grave. Where dependent on intracranial disorder optic neuritis is usually double, but an interval of weeks, and even months, may intervene between its appearance in one eye and its supervention in the other.

In a few cases the origin of the neuritis is traceable to a post-ocular but intra-orbital cause, such as a tumour compressing the nerve. In another class of cases it is an accompaniment or the sequel of some acute general disorder, as diphtheria, rheumatic fever, or one of the exanthemata; and in a third class its subjects are young chlorotic females.

The treatment will vary with the cause. If this is presumably a post-ocular syphilitic gumma, potassic iodide or mercury should be given. If the patient is a feeble convalescent from an acute general disorder or a chlorotic girl, iron with cod-liver oil deserves the preference, and mercury should be given in small doses, if at all. The local abstraction of blood with the artificial or natural leech appears to be beneficial where there is great vascular turgescence in the papilla.

Atrophy of optic nerve. (Plate II. fig. 1.)—This is a sequel of a coarse neuritis, and it also occurs unpreceded by such coarse inflammatory alterations as are recognisable with the ophthalmoscope, often in association with spinal disorder. It is in some instances the direct consequence of unduly heightened intracocular pressure. It has been observed in association with exhaustion depending on sexual abuse, and also in connection with inordinate use of tobacco. When it is the result of neuritis, the contour of the nerve is often blurred and wanting in the sharpness of definition which stamps simple atrophy; and until a very considerable interval has elapsed since the occurrence of the neuritis, the papilla is greyish rather than white; whereas in simple atrophy, contrasting strongly with the redness surrounding it, the optic nerve at once attracts attention by its extreme whiteness, which resembles that of ivory, rather than the creamy or faintly pinkish tint which has been described as characterising the nervous tissue in a state of health. These dense-looking, homogeneous nerves have undergone *white atrophy*, and have lost the greater portion of their true nervous element, little more than the fibrous tissue remaining. (Plate III. fig. 2.) The appearance of such a homogeneous, white, optic nerve, at once assures the practised observer that the case is quite beyond recovery.

The surface of such wasted nerve is depressed ; it slopes gently from the border towards the centre. The vasa centralia are contracted or finally even obliterated, though the veins are often during some time unnaturally conspicuous through their strong contrast with the blanched nerve.

Treatment in cases of advanced atrophy is useless. At an earlier stage the removal of inordinate pressure where this exists, as in glaucoma, may stay its progress. When associated with sexual excess, or with the inordinate use of tobacco, abstinence and the internal exhibition of strychnine and iron will in some instances obtain unexpected improvement, and these drugs also appear occasionally to effect some improvement in the atrophy which attends spinal disorders. The general improvement in the patient's health where the exhibition of these drugs appears beneficially to influence the atrophy of the nerve, suggests that their influence upon the nerve is indirect.

Retinitis.—The ophthalmoscopic signs of retinitis are essentially of the same order as those which mark neuritis; they are loss of transparence, swelling, and engorgement of the blood-vessels, producing opaque greyish patches often blotched with a rusty stain from admixture of extravasated blood, and dilatation with tortuosity of the veins, which together with the arteries appear interrupted where overlaid and concealed by some thickness of opaque retinal tissue. The heightened blood-pressure upon their walls produces minute aneurismal dilatations, which, bursting, are the source of minute capillary hæmorrhages, and it even causes rupture of veins occasioning not infrequently large extravasations which when recent appear as crimson blotches and brushes. Their form depends on the seat of the hæmorrhage. The escaping blood takes the lines of least resistance, hence hæmorrhages in the inner layers are usually brush-like, long splashes, and in the outer layers they have the form of round spots and blotches.

A detailed account of all the forms of retinitis which authors have described, is beyond the scope of this article: it must suffice to briefly notice the more prominent. In one form of retinitis (*hæmorrhagic retinitis*) the retina is more or less closely spotted with blotches and brushes of extravasated blood, between which the transparence of the coat is impaired only in a degree indicating a very slight amount of edema or exudation. Repeated hæmorrhages are usual. The most recent are crimson, the least recent are buff-coloured, and between these extremes every shade of red and rust colour is noticeable. The subjects of this form of retinitis are often middle-aged and elderly persons.

In another form the retina around the optic papilla becomes grey and opaque; the opaque area is dotted with minute hæmorrhages which may coalesce in larger spots, and the papilla itself is similarly stippled. The veins are very turgid and tortuous, and concealed where they dip deeply away from the inner surface of the coat. Soon small white dots appear in and around the opaque grey parts, often coalescing in larger patches; and, which is very characteristic, a peculiar radial grouping of glistening white dots, to which attention was first called by Liebreich, may be noticed at the macula lutea. Frequently, however, the ophthalmoscopic picture is less typical than that just described, deviating in the greater or less prominence or in the combination of the details. This form of retinitis (the *albuminuric*) occurs in connection with renal disease, and its subjects are often in such apparently good health that, until suspicion is excited by the retinal disorder, the existence of kidney disease is undiscovered.

The progress of the retinal disorder is in intimate relation with that of the kidney, frequently receding when this improves, and augmenting when this increases. Such fluctuation of albuminuric retinitis may be frequently observed in women during and between successive pregnancies. In such patients, especially during the later months of pregnancy, the retinal disorder greatly increases, and after delivery all signs of retinitis may disappear. As regards treatment, mercury is inadmissible, and leeching does not appear to influence the disorder. The tincture of sesquichloride of iron is thought to be useful.

Syphilitic retinitis.—Another form of retinitis occurs in syphilis. There is more

exudation, producing larger and less defined opaque grey blotches, and hæmorrhages are a less prominent feature than in the forms already described. It is often associated with, and not infrequently consecutive upon, choroiditis and iritis. A larger number of cases are met with in the early than occur in the latest stage of constitutional syphilis. For the treatment mercury is preferable to iodide of potassium.

Chlorotic retinitis.—Retinitis is so frequently seen in young females suffering from chlorosis, that a causal relation may be not unreasonably inferred to exist between this and the retinal disorder. The ophthalmoscopic signs do not essentially differ from those of the syphilitic form, but chlorotic retinitis is more often combined with neuritis than is observed to occur in syphilitic retinitis, and choroidal and iritic complications are absent. The age and circumstances, and the entire absence of other symptoms of syphilitic taint, absolutely exclude the idea of a syphilitic origin in many of these cases. If treated early, recovery is not very infrequent. Iron is most useful.

Retinitis pigmentosa. (Plate II. fig. 2.)—The presence of pigment in the retina stamps this form of retinitis. The pigment occurs in irregular star-like aggregations and nets of lines, often following the course of the larger blood-vessels. Whilst not denying that it may be formed within the retina, the belief is strongly held by some that the pigment is derived from the choroid, which is strengthened by the frequent concurrence of unmistakable signs of choroiditis. The disorder begins at the periphery of the retina and creeps backwards towards the optic nerve, leaving the retinal tissues atrophied, the obliterated larger blood-vessels appearing as opaque lines. This form of retinitis usually begins in very early life, it often affects several members in a family, and it has been thought by some to be more common in the offspring of marriages of near blood relationship. The centripetal progress of the disorder in the retina produces a corresponding contraction of the visual field; and a person so affected has difficulty in finding his way about after dusk, whilst his central vision may yet be so good that he reads, without trouble, ordinary type. In the advanced stage of the disorder central vision is also blunted, and finally lost when the parts of the retina around the posterior pole of the eye ball, including the macula and optic papilla, are atrophied.

This form of retinitis is not controlled by any yet known treatment.

RETINAL HÆMORRHAGES.

Extrusion of blood, either from the retina or the choroid, constitutes, I need hardly say, one of the most serious accidents to which those coats are liable. The blood may be effused in consequence of a blow on the eyeball, or it may escape spontaneously from a distended vessel giving way, as in ordinary apoplexy. The occurrence of hæmorrhage in neuritis and retinitis has been already noticed.

It is remarkable that rupture of a retinal vessel sometimes occurs without any of the symptoms which one might expect would accompany it—such as giddiness and other signs of cerebral disturbance. I have seen many cases in which a dimness or cloudiness has suddenly overspread one eye, while the patient, in apparently good health, was quietly engaged in reading or writing; no pain or uneasiness of any kind accompanying the attack, the iris retaining its mobility, and even the conjunctiva and sclerotic showing no trace of increased vascularity. The patient finds that a considerable portion of his field of vision has become a total blank as regards perception of objects; while, perhaps, he still retains the power of dimly discerning those which happen to fall on some limited portion of the retina. If such a case is examined within a few hours or even a few days, after the rupture of the vessel, the fresh red colour of the effused blood will at once be recognised. If it is one of the radiating vessels of the retina that has given way, the prognosis will be much more favourable than if the hæmorrhage had come from the choroid; for, in the former case, the tissue of the retina, although for a time overspread with blood, and so rendered incapable of receiving visual impressions, may have escaped any serious

disintegration; whereas, if the blood has proceeded from the choroid, it may have actually ruptured the retina, and irreparably destroyed that portion of it as far as its function is concerned. The presence of clots freely floating in the vitreous humour would be a still more unfavourable sign, as it would prove that the tissue of the vitreous body had, to a certain extent, been broken up. This latter complication more frequently results from blows on the eyeball than from spontaneous apoplectic extravasation.

No one who has had a little practice with the ophthalmoscope can find any difficulty in detecting a recent extravasation of blood on the surface of the retina; but the recognition of the changes which mark the site of old extravasations is often extremely difficult. I have already noticed the cases in which a rupture of choroidal vessels breaks up and destroys a limited portion both of the choroid and retina, leaving either a well-defined space of white sclerotic, or a patch of dark pigment, to mark the site of the disruption. But a less extensive extravasation, originating in the rupture of a superficial vessel of the retina, may leave such faint traces as almost to escape observation. Sometimes the site of the rupture is marked by a slight brownish stain, in other cases by a faint mottling of the retinal surface; while a more extensive extravasation may so far damage the retina as to leave in after-years a linear or stellated cicatrix (if one may so term it), of a lighter colour than the surrounding tissue.

EMBOLISM OF THE CENTRAL ARTERY.

The obstruction is in a trunk of the artery before its subdivision, or in one of the branches. It reduces vision suddenly to bare quantitative perception of light involving the whole or part of the visual field. Where the trunk of the artery is plugged the optic papilla appears blanched, and the *vasa centralia*, much contracted, are nearly emptied of blood resembling white threads, in which slender red cylinders are intercalated where they still contain a small quantity of blood. When the embolus blocks one of the arterial branches, similar appearances are observed in the area within which it is distributed. The macula lutea soon after becomes opaque, forming a dull greyish oval patch enclosing a small central red spot, which is deceptively like hemorrhage, but is really the choroid, apparent here through the thin retina.

DETACHED RETINA.

(*Solutio retinae; Hydropsie sous-rétinienne*).

Serous effusion between retina and choroid may occur as a result either of acute or chronic inflammation of the choroid; or it may be produced by traction upon the inner surface of the retina, relatively lowering the pressure upon the outer surface of the choroidal capillaries. *Chronic effusion between the retina and choroid may take place in the most gradual and insidious manner, so as only to manifest itself by impairment of vision, unattended with any pain or external signs of inflammation. Detachment of the retina from the choroid not infrequently supervenes on sclero-choroiditis posterior in high degrees of myopia in advanced life.*

When the retina has become detached to a very considerable extent, a corresponding portion of the field of vision becomes a total blank, so far as perception of objects is concerned; while that portion of the retina which remains in apposition with the choroid may still distinguish even small objects, although in an imperfect and partial manner.

There are no external signs by which we can ascertain the existence of effusion beneath the retina. The ophthalmoscope alone enables us to detect it.

The effused fluid may either exist in such a small quantity as barely suffices to impart a cloudy appearance to a limited portion of the retina; or it may have detached a considerable extent of the retina, or even the whole of it, from its connection with the choroid.

The more limited effusions frequently occur in the immediate neighbourhood of

the optic nerve. They tend to sink to the most dependent part. At first sight they appear as greyish or cloudy patches in the midst of healthy tissue, and the retinal vessels which are spread out over the rest of the fundus of the eye appear to be lost when they arrive at the edge of the patch. This appearance is owing to the fact of the vessels being raised up by the effusion beneath them, so that they are on a plane different from that of the vessels of the healthy retina. A slight movement of the convex glass, when the indirect method of ophthalmoscopy is employed, will at once bring into the focus the vessels overlying the effusion.

When a large portion of the retina has been separated, it presents the appearance of a lobular mass, of an opaque greyish colour, contrasting in a remarkable manner with the reddish surface of that part of the fundus oculi where the retina still retains its natural position and transparence. Sometimes the lobular mass may be observed to oscillate with each movement of the eye, and when brought into focus upon its surface are seen ramifying vessels, the displaced veins of the retina, which are lost to view where they ~~are~~ between the lobules, and thus appear to be frequently interrupted.

When almost the entire retina is detached from the choroid, the appearances under the ophthalmoscope are at first very difficult to understand. The whole fundus of the eye appears at one moment of a dull pearly grey, as if covered with a milky gelatinous deposit; then the white disc of the optic nerve comes for an instant into view, and then again a sudden turn of the eyeball affords a glimpse of some very limited portion of undisplaced transparent retina, where the fundus oculi still dimly reflects the luminous rays which fall upon it. Not infrequently the view is still farther confused by floating bodies dispersed through the vitreous humour.

The course of this disorder is often very chronic, and may be interrupted, but its tendency is progressive; and though exceptionally the effusion may disappear and the retina become reapplied to the choroid, much more frequently the whole of the nervous tissue is eventually stripped from the choroid and the visual field curtailed until sight is finally lost.

Strict rest of the eyes and avoidance of all strain should be enjoined. Iodide of potassium and corrosive sublimate are frequently prescribed, but they do not seem to avert the final result. The failure of internal remedies has led to attempts to restore the balance of pressure on the two surfaces of the retina by puncturing or tearing this freely with one or a pair of needles introduced through the choroid for the purpose of making a free communication between the space occupied by the effusion and the vitreous humour. The immediate results of this are occasionally very promising; unfortunately they are not permanent, and the operation has in a few instances produced increased choroiditis and hastened the destruction of sight.

TUMOURS OF THE CHOROID AND RETINA.

The majority of primary tumours of the eyeball are referable to sarcoma and its variety glioma, and but few can be referred to carcinoma in its present restricted sense. The sarcomatous and carcinomatous tumours begin usually in the choroid, and glioma takes its origin in the connective substance of the optic papilla or retina. The occurrence of glioma is almost without exception restricted to early childhood, whilst sarcoma and cancer are unusual before adult life. With respect to glioma no causative antecedents are known, but sarcoma and cancer both so frequently arise in eyes which have been spoiled by inflammation that such inflammatory disorganisation of the ocular tissues may fairly be considered a predisposing cause. In their course and end glioma and sarcoma of the eyeball are as destructive as carcinoma.

As glioma affects children of very tender years, not infrequently whilst still in arms, its earliest symptom is not conscious loss of sight, but often the mother or nurse is first made aware of something unnatural by a bright yellowish reflex from the bottom of the eye shining through the pupil. This occurs when the growth has advanced so far in front of the posterior principal focus of the eye that luminous rays reflected by its summit emerging from the pupil undergo dispersion. If it be now examined with the ophthalmoscope, the extent and form of the tumour can be

recognised. Continuing to grow and to infect all the structures with which it comes into relation, the tumour distends the eyeball, which becomes hard and painful. The vitreous humour loses its clearness, the lens is thrust against the cornea, this in time grows cloudy and then sloughs; after which, released from constraint, the tumour sprouts out of the front of the eyeball and forms a large fungating mass which may protrude to a considerable distance between the eyelids. Whilst this is proceeding, the glioma often infects and passes through the sclerotic where this is thinnest behind the insertion of the tendons of the recti muscles; it escapes along the foramina of exit of the *venæ vorticosæ*, and it also creeps backwards along the optic nerve, entering the cranium and infecting the chiasma. It is not very unusual for glioma to spring up in the other eye. Should the child survive a sufficient time the diploe may become the seat of secondary knots, and in very rare instances such knots have been found in distant viscera, *e.g.* liver; but usually this is anticipated by death. Early excision of the eyeball, including, if the disorder is at all advanced, the other orbital tissues, with section of the optic nerve short in front of the bony foramen, will often afford a respite, but quick recurrence very usually takes place. The ophthalmoscopic signs of a choroidal sarcoma or carcinoma do not widely differ from those of glioma. Seated primarily in the choroid and often pigmented (melanotic), these tumours do not usually betray their presence by the bright yellow reflex so characteristic of glioma. They also often lead to detachment of the retina from the choroid, which still further conceals their presence and may lead to mistaken diagnosis. The tension of the eyeball here will sometimes give a hint. In simple detachment of the retina it is not usually excessive, but often unnaturally low; whereas in retinal detachment complicating a choroidal tumour, the tension, gauged by the hardness of the eyeball, is generally greater than normal. The course and final result are so similar to those of glioma that it is unnecessary to dwell upon them. Early and free excision of the eyeball alone offers a long immunity from return. In one instance within the reviser's experience this respite lasted seven years. Even when the new growth has infected the orbital tissues, excision may still be practised in the absence of symptoms indicating intracranial extension. The free use of zinc-chloride for the purpose of destroying small portions of tumour which may have escaped removal with scissors or knife, is here strongly recommended. In these cases the liver is the organ in which secondary growths are most often found.

CHAPTER VIII.

VISUAL DISORDERS.

AN anatomical classification of eye-diseases—the arranging of them, that is to say, according to the changes of structure which cause the impairment of sight—has such obvious advantages that it has become almost universal among ophthalmic writers; but it has the inconvenience of offering no heading under which to place certain defects which cannot be precisely demonstrated as originating in any one part of the optic apparatus.

Of this kind are the various luminous appearances depending upon some temporary disturbance of circulation; Chromatopsia, Teichopsia; occasional obscuration of half the field of vision (*Hemiopia*); the condition termed *Hemeralopia*; congenital inability to distinguish certain colours; spectral illusions, &c.

Hemiopia, Hemiopia.—Obscuration of half of the visual field, not to be taken strictly literally, when permanent, depends on defect in the corresponding hemisphere of the retina, or of the nerve-bundles ending in this, or else in their central connections. Thus in detachment of the retina, implicating its most dependent segment, the corresponding upper part of the visual field above the level of the eye is often blotted out, and a similar curtailment may be caused by a retinal hæmorrhage. Transient hemiopia is often an initial symptom of megrim, and in such cases no morbid appearances are recognisable with the ophthalmoscope. The ocular symptoms

begin with an obscuration compared to that which follows looking at the sun. Usually this starting from one point, in the visual field spreads centrifugally until it blots out a considerable extent of it. The margins of this scotoma are in some instances fringed with an indented border of luminous colours which rapidly oscillates. In such cases the disappearance of the ocular symptoms is followed by intense sick headache. For an excellent discussion of this subject the reader is referred to 'Lievig on Megrim and Sick Headache.'

HEMERALOPIA.

Hemeralopia—literally 'day-sight'—is a term used to designate a peculiar form of intermittent blindness, the subjects of which see perfectly in broad daylight, but lose all power of perceiving objects as soon as the sun has set, and twilight commences. The persons in whom the affection is most frequently met with in this country are those just returned from sea voyages, especially from the East or West Indies. It is also frequent, I am told, among the natives of the inland parts of India, who attribute it, as our own sailors do, to sleeping exposed to the moonbeams.

The real cause of hemeralopia appears to be exhaustion of the nervous power of the retina from over-excitation by the sun's rays, so that the part is rendered incapable of appreciating the weaker stimulus of twilight or moonlight. That this is the true explanation of night-blindness is demonstrated by the fact that night-blind sailors who cannot see to find their way about on decks see well in the cabin where a bright lamp is burning. There are not any characteristic ophthalmoscopic signs; the fundus oculi does not in this disorder exhibit any morbid appearances. Exposure to tropical light, however, is not the sole cause of the affection; for I have met with it in persons who had never quitted the temperate regions of the globe; but in most of these latter cases the complaint had shown itself after long voyages, which had subjected the patients to exhausting toil and exposure to severe weather, while deprived of a proper supply of fresh provisions and vegetables.

In these latter cases, I have commonly found that a few weeks' residence on shore, with a mixed vegetable and animal diet, and the use of quinine, has restored vision to a healthy state.

Nyctalopia—'night-sight'—would imply inability to see by daylight, the exact converse of hemeralopia. In a certain sense, patients affected with that irritable form of corneal inflammation commonly called 'strumous ophthalmia,' might be termed nyctalopic, so unable are they to bear strong light, and so willing to open the eyes and look about them in the dimness of twilight; but, apart from inflammation, I have never met with nyctalopia to the extent described by authors; and I am inclined to consider the affection an imaginary one, invented, as it were, to form a companion disease to the hemeralopia just described.

COLOUR-BLINDNESS.

Imperfect perception of colours in slight degrees is a very common defect. In high degrees it was, until lately, thought to be of very exceptional occurrence; but recent investigations have revealed that in Europe, and in the United States, inability to recognise some colours is present in so high a degree, in about four persons in one hundred, as to render the employment of such individuals perilous to public safety where this depends on the prompt and accurate recognition of coloured signals. Holmgreen,¹ in which he is followed by J. Jeffries,² distinguishes three forms, in relation to the three fundamental colours; red, green, and violet (blue) blindness. The red-blind person is sensible of two fundamental colours only in the solar spectrum, which are green and violet. Spectral red and yellow appear to him greens. The green-blind individual perceives only the red and violet (blue) in the spectrum; he confounds yellow with red, and green with violet. The violet-blind person mistakes blue and violet for green.

¹ *Die Farbenblindheit in ihren Beziehungen zu den Eisenbahnen und der Marine.*

² *Colour-blindness; its dangers and its detection.*

In the examination of persons for the detection of these defects, those methods which require the individual under examination to match but not to name colours are to be preferred. Such a method is that of Holmgreen, which has been very widely adopted. The examiner selects from a large number of skeins of Berlin wool, which can be had in every shade and variety of colour, a few as tests, and requires the person under examination to place with these those which appear to him to be of the same colour and shade. If a pure light green has been selected as the test skein, and the person who is being examined places together with shades of this other skeins of greys, reds, yellows, or blues, he is manifestly colour-blind. He is next asked to match a purple skein. If, together with other similarly coloured skeins, he puts others coloured blue and violet, he is red-blind; whilst if he confounds with purple greens and greys he is green-blind. As a control test a bright, pure red skein is chosen. This a red-blind person matches with shades of green and brown which appear to a normally sighted examiner darker than the red, whilst a green-blind person chooses out opposite shades which appear to the examiner darker than the bright red test. A violet-blind person confounds with the purple skein others of red and orange. In the greater number of instances colour-blindness is a congenital and irremediable defect, but it is occasionally acquired; its accession, after severe head injuries and vascular disorders of the optic nerve and retina, is a well-established fact.

CHAPTER IX.

DISEASES OF THE VITREOUS BODY.

BEFORE the invention of the ophthalmoscope, little was known about the morbid conditions of the vitreous humour. It was frequently found to become diffuent (*synchysis*) after injuries to the eyeball, and during the progress of certain chronic inflammations; and it was assumed to play an important part in glaucoma. The ophthalmoscope presents to our view a great variety of morbid products in the humour, which it is difficult to observe with accuracy, on account of the rapidity with which many of the flakes, filaments, and corpuscles float about with every movement of the eye.

When *hemorrhage* occurs from the ciliary processes, or from the superficial vessels of the retina, or bursts through the retina from the choroid, a portion of the clot not infrequently becomes entangled in the vitreous humour, and forms an irregular, filamentous, black looking body floating to and fro across the illuminated field of the ophthalmoscope.

In *syphilitic inflammation* of the deep tissues, the vitreous humour loses its perfect transparency, and becomes turbid; and in severe cases, flakes of lymph are seen freely moving about in it, like tangled blackish threads.

Many of these and similar opacities are products of the proliferation of the embryonic connective-tissue corpuscles which throughout life persist in the membranous dissepiments of the loculi of this body. In suppurative inflammation the pus-corpuscles which pervade this humour are believed to be offspring of these corpuscles.

In syphilitic cases it is sometimes surprising to observe how much such opacities clear up under the exhibition of mercury.

A very singular phenomenon connected with the vitreous humour is that termed *sparkling synchysis* ('*synchysis étincelant*'), produced by the presence of crystals of cholestérine, which at each movement of the eye appear as innumerable brilliant points, like the finest gold-dust, sparkling in the dark area of the pupil. When the eye is kept at rest these crystals gravitate to the bottom of the mingled aqueous and vitreous humours, some sinking down behind, and some in front of, the iris.

Cysticerci.—Perhaps the most striking phenomenon connected with the vitreous humour is the presence of entozoa, either freely floating within it, or protruding

into it from the surface of the retina, to which they are attached. By far the greater number of cases of this kind which have been recorded are to be found in foreign journals, for hitherto only a very few have been observed in this country.¹

Of twenty cases reported at the date of the last edition of the work in various numbers of the *Archiv für Ophthalmologie*, the majority appear to have been under the care of A. von Graefe. In eight cases the cysticercus was either embedded in the very tissue of the retina, or firmly adherent to its surface; in six cases the creature appeared to be behind the retina; while in six others it was quite detached, and floated freely in the vitreous humour. This latter circumstance induced Graefe, in two instances, to attempt its removal; in the first case making an incision in the sclerotic and passing in a forceps through the wound; in the second adopting a slower and more complicated proceeding. First, a portion of the iris was excised, so as to make a large artificial pupil; then, when all irritation had subsided, the lens was extracted through a flap-section of the cornea; and lastly, after a considerable interval of time had been allowed to elapse, a forceps was introduced through a fresh opening made in the cornea, and the cysticercus grasped and drawn out.²

From a review of all these cases, it appears almost certain that the cysticerci found loose in the vitreous humour had attained that position by perforating the retina, having been originally formed between that tissue and the choroid, in which situation it seems that all the cysticerci above described were originally developed.

In a more recent volume of the *Archiv*, Graefe gives the total result of his experience as to the occurrence of cysticercus (xii. 2, 174, 1866). During thirteen years 80,000 patients had attended his clinique, and among them rather more than 80 cases of cysticercus in the deep tissues of the eye had been observed: 3 had been seen in the anterior chamber; 5 under the conjunctiva, 1 in the substance of the lens; 1 in the orbit. The ages of the patients varied from eight years to seventy.

I believe it has been well ascertained that the inhabitants of Northern Germany are more liable to tape-worm than those of the British Islands, and this circumstance would account for the fact of the cysticercus having been so much more frequently met with in the former country.

Musca volitantes.—The little threads and spots which, by some persons, are seen to float and glide over their field of vision, were formerly attributed very commonly to congestion of the choroid. Tyrrell, for instance, assigned as their cause 'a preternatural dilatation of some of the delicate vessels' of the part. It seems strange that any one could overlook the fact that *fixed* bodies—which dilated vessels of the choroid must be—if they pressed upon the retina so as to impair its function, would suggest to the patient the idea of *fixed* spots in the field of vision, which could only appear to move when the eyeball itself was set in motion. The spots known as *musca volitantes*, on the contrary, change their position whenever the eye is suddenly moved; and when the eye is again fixed, the spots still continue for a time to float about in various directions, eventually appearing to descend, as if sinking in a fluid.

They are most commonly met with in short-sighted subjects, and are quite compatible with life-long continuance of the acute powers of vision which such persons frequently enjoy. They are usually first noticed between the ages of twenty and thirty; and when they have begun to attract the patient's attention, they appear rapidly to increase in number. This apparent increase is partly due to the fact that, by anxiously watching them, the patient soon acquires a habit of bringing fresh bodies into view.

If the eye be turned towards a clear sky or a bright cloud, and then kept steadily

¹ Teale gives the history of a case occurring in his own practice in 1804 (*Ophth. Hosp. Reports*, vol. v. p. 318). Bowman reports another (op. cit. vol. iii. p. 324). Hulke, in dissecting a disorganised and irritable eye, found a cysticercus between the choroid and retina.

² A case of cysticercus in the vitreous humour is related by Desmarres, *Traité théorique et pratique des Maladies des Yeux*, 2nd edit. 1858, vol. iii. p. 756. Another by Williams in the *Cincinnati Lancet and Observer*, May 1858. See Liebreich's *Atlas*, tab. vii. figs. 5 and 6.

fixed, the spots appear to sink slowly downwards, just as filmy particles would sink in a liquid which had been shaken and then allowed to rest. A sudden turn of the eye will again cause the little bodies to disperse for a moment, and when the eye is once more fixed, they slowly descend as before.

So long as the patient steadily concentrates his attention on any external object, the *muscæ* are not seen; but if he accidentally catches sight of one of them, the whole field of vision at once becomes crowded with them.

The best way of examining the floating bodies is for the patient to look directly downwards upon the illuminated field of a microscope. They will then be recognised as beaded filaments, variously twisted and bent; sometimes appearing as loose knots of coiled-up fibres entangled together. When thus grouped they have a greyish colour, but when a single filament is examined it is seen to be made up of highly-refractive globules, varying in form and size. Sometimes a filament may be seen to bend, and again become nearly straight, or to turn in such a manner as to present itself in a foreshortened position. This latter circumstance proves that the bodies float freely in a fluid, and are not situated, as some have supposed, upon the surface of the cornea. This is still further proved by the fact that the blinking of the lids has no effect whatever upon the position of the *muscæ* in the field of vision. If, when the lids are closed, the eyes are turned towards a strong light—exposed to sunlight, for instance—the *muscæ* can still be seen, and their movements will be just as free as when they were observed with the eyes open.

Some interesting experiments were made on himself by Mackenzie,¹ to determine the seat of *muscæ volitantes*; but the most conclusive researches as to their nature are those by Jago,² who has satisfied himself that these disquieting spectres are, in fact, nothing more than the beaded filaments of the vitreous body itself. The normal network of these filaments, he says, can be seen by any one who knows how to look for them—under certain conditions, I presume, of impressibility of retina. Those filaments which, from being tangled together in irregular masses, form such annoyances to the patient, would appear to be the filamentous network in a disintegrated state.

There are few phenomena which give rise to more alarm in patients' minds than *muscæ volitantes*. A vague notion that they are the forerunners of amaurosis or cataract is almost universal; and even medical men are apt to confound these floating *muscæ* with the moving cloudy shadows resulting from effusions of blood or lymph within the vitreous humour, or with the fixed spots betokening that some limited portion of the retina has become insensible to light. A careful attention to the appearances of the *muscæ volitantes*, as I have described them, will enable the patient to convince himself of their real nature; and the surgeon may console him with the assurance that, although incurable, they are perfectly compatible with excellent and enduring sight.

CHAPTER X.

DISEASES OF THE LENS AND CAPSULE.

In a state of health the lens and the membranous capsule enclosing it are perfectly transparent. In early life they are also quite colourless; but after the age of thirty the lens in most persons begins to assume a pale yellow tinge; and this gradually becomes more marked as age advances, until in old subjects it frequently acquires the colour of amber.

Any loss of transparency in the lens, whether affecting the whole or only a

¹ First in the *Edinburgh Med. and Surg. Journal*, for 1865; and again in his *Practical Treatise*, &c., 1864, p. 951.

² *Entoptics, with its uses in Physiology and Medicine*, 1864, p. 93.

portion of it, constitutes *cataract*; and in strictness this term should be limited to changes in the lens and its capsule. To call an opaque inflammatory effusion in the area of the pupil a 'spurious cataract,' is to introduce a loose and uncertain terminology, which can only give rise to confusion in our descriptions of disease.

Abnormal position of the lens.—The 'suspensory ligament,' which is attached to the capsule all round the margin of the lens, maintains it in a fixed position. A blow on the eye sometimes ruptures a portion of this ligament, and allows the lens to become tilted backwards and forwards. If the ligament is detached to a considerable extent, the lens sways to and fro with every movement of the globe, and vision is much confused. Eventually, under such conditions, the lens becomes opaque; but I have seen cases in which it remained transparent for a very considerable time.

It appears that the suspensory ligament is liable to a congenital defect, whereby the lens, instead of maintaining its normal position, undergoes displacement in a lateral direction, so that its centre no longer coincides with the centre of the pupil. A curious instance of this malposition of the lens occurred in a mother and three children who came under my care. In the mother, and in one of the sons, both lenses were displaced upwards and inwards; in another son, directly inwards; and in the third, directly upwards. In none of these cases did the lenses deviate, or only in the slightest possible degree, from their normal transparency.

[This condition is not very infrequent. In some instances the refraction through the lens is myopic, whilst refraction through the interval between the edge of the lens and margin of the dilated pupil is hypermetropic, which causes much confusion of sight in subdued light. As observed by Mr. Dixon, it often affects several members of a family, and it is hereditary.—J. W. H.]

(CATARACT.

This term, as I have already observed, should be strictly limited to denote partial or complete opacity of the lens.

The expression capsular cataract has of late years been objected to, because the capsule itself never becomes opaque, we, however, retain it, because we cannot in practice distinguish between opaque accretions upon the surfaces of the capsule and the membrane itself.

Opacities of the lens appear to be due to molecular degenerations of its tissue, induced by impairment of its nutrition. The causes of cataract, whether remote or proximate, have hitherto received no satisfactory explanation. The fact that the lens may be opaque at birth, or may become so in old age, at once proves under what widely different conditions the disease is developed.

In all countries, cataract is a frequent accompaniment of advancing years; and neither social position nor peculiarity of employment exempts the aged from being liable to it.

The surgeon must constantly be on his guard against being too much impressed with the mere existence of opacity in the lens, as if it were altogether an independent disease.

Various inflammatory conditions of the eyeball may eventually produce cataract, but in such cases there are usually some signs of disease in other tissues, as well as certain peculiarities in the position or appearance of the lens itself. Old adhesions between the pupillary margin and the anterior capsule—a bulging forward against the cornea of the iris and lens, or their receding too far backwards, so as to produce an unnaturally large anterior chamber—an irregularly dilated and fixed pupil—a tremulousness of the lens whenever the recti muscles are put in action—total loss of perception of light—such are the more striking conditions which at once would lead us to institute searching inquiries into the earlier history of the case, or to regard the cataract as unsuited for operation.

Classified according to the time at which they appear, cataracts are congenital, infantile, and senile; in relation to their cause, they are traumatic and idiopathic;

with reference to their consistence, hard and soft; and in respect of the seat of the opacity, they are cortical, intermediate, and nuclear.

The reader need not be detained by a long account of the *subjective* symptoms which attend cataract; for the detection of the disease depends wholly upon a careful examination of parts lying open to our observation. A full detail of subjective symptoms is, no doubt, very useful in ascertaining the morbid condition of a structure wholly concealed from our view; but this is not the case with the lens, and if we suspect opacity to exist, we have simply to look for it.

It must always be remembered that simple opacity of the lens, however far advanced, never deprives a patient of perception of light, provided the retina is sound. Indeed, in the great majority of instances, a patient with no other disease in the eye but an opaque lens, will not only readily perceive the shadow of a hand, or other object, passing between him and the sky, but, with his back to the window, will perceive the light reflected from a sheet of paper, although he may be quite unable to detect the form of the reflecting surface. Many patients, with densely opaque lenses, will, in the same position, recognise well-illuminated coloured surfaces, such as bright red or yellow, or will even discriminate between yellow and white.

A more or less marked dimness of sight, uniformly involving the field of vision—coming on gradually, and without inflammation, unattended with any impairment of motory power in the iris—such would be the symptoms which would make us suspect the existence of cataract. Our examination should be conducted in the following way:

The patient should be placed close to a window admitting bright daylight—not direct sunlight—and care should be taken that the light does not fall upon the cornea from more than one window, and that reflections from mirrors and other polished surfaces do not interfere with the single ray which should pass into the pupil. A convex glass of an inch focus should be used as a condenser, to concentrate light upon the surface of the patient's lens, while we explore it with the naked eye. In this manner faint streaks of opacity may be detected, which would otherwise escape us. Each eye must be separately examined.

The pupil having been fully dilated *with atropine*, we repeat our examination as before, with the aid of concentrated daylight, carefully illuminating and exploring the extreme margin of the lens, and, if its body be sufficiently transparent, lighting up and examining its posterior surface. In this manner the faintest streaks of commencing cataract may usually be detected; while dense patches along the margin of the lens, opaque striae converging along its anterior or posterior surface, delicate lines radiating from the centre or the uniform haze of a cloudy nucleus, can hardly escape detection.

These examinations should be controlled by the direct method of ophthalmoscopy with the precaution of using a very subdued illumination. In most cases, the opaque striae of a commencing cataract are then seen as radiating black lines, while a hazy nucleus assumes the appearance of a dark cloud in the centre of the pupil.

While cataract is still in a very early stage of development, it is so important to ascertain the condition of the retina and choroid, that in every case the ophthalmoscope should be used to complete our diagnosis.

By examining the deep tissues we sometimes detect in them morbid conditions, which would induce us eventually, when cataract had become complete, to abstain from operating; or, if an operation were deemed desirable, it would be undertaken on the full understanding that only partial success would be attainable.

CONGENITAL CATARACT.

This opacity may exist in very different forms.

1. The slightest form is that of a small white central dot on the anterior face of the lens (*Cataracta centralis*). This dot consists of a minute portion of earthy matter deposited in the most superficial portion of the lens, just within the capsule. In cases of this kind the rest of the lens commonly remains throughout life trans-

parent, and the patient is often unconscious of any defect of vision. Occasionally, however, a few faint white lines are seen radiating from the central dot. If the rest of the lens remains transparent, this slight form of cataract should by no means be treated by operation.

2. Sometimes, instead of forming a minute central dot, the opacity is so large as to occupy nearly the whole area of the pupil, when in its contracted state. It projects forwards in the shape of an obtuse white cone, and appears to adhere by its base to the anterior surface of the capsule. This, however, is not really the case, the cretaceous mass being imbedded in the superficial portion of the lens, and covered by the transparent capsule. The term *Cataracta pyramidata* has been given to this congenital form.

3. Another form of congenital cataract is that in which the nucleus is opaque, while the peripheral portion remains transparent. In the contracted condition of the pupil this transparent portion is hidden by the iris, but it comes into view when the pupil is widely dilated. In the contracted, or but slightly dilated, state of the pupil, its entire area is occupied by a greyish-white opacity. When inspected with the ophthalmoscope by the direct method, the opacity appears equally dense throughout, or is denser centrally than at the periphery. When the pupil is widely dilated with atropine, this opacity is seen to be surrounded by a perfectly black area, and through this clear ring-shaped space the patient has tolerably clear vision. Those who examine such cases for the first time are apt to imagine that the opaque nucleus which they see really constitutes the whole lens, shrunk and contracted to an unnaturally small size, and that the dark ring-shaped space is altogether unoccupied by lens-tissue. Occasionally a few white lines are seen to traverse this space, passing from the opaque nucleus to the outer margin of the lens. When such a nuclear cataract is broken up with the needle, in the operation for solution, the real nature of the case is made manifest, and the peripheral portion of the lens soon becomes as opaque as the nucleus itself.

If cases of this kind are not operated upon in early life, the patients, although very short-sighted, continue for many years to enjoy considerable powers of vision; but usually, towards the age of forty, if not sooner, the peripheral portion of the lens undergoes a change, and gradually becomes opaque.

4. A form of congenital cataract, much more rare than that just described, consists of a very faintly-striated opacity of the nucleus, unaccompanied by that chalky-white central patch which renders the ordinary congenital cataract so conspicuous and so easy of diagnosis. Several instances have come under my notice, in which this rarer kind of cataract has remained undiscovered until the patients were of an age to be sent to school, when their inability to read ordinary type has caused their friends to seek advice.

5. A very common form is that in which the nucleus and the cortex of the lens are transparent and the opacity is limited to an intermediate zone. Occasionally, more than one such zone is present. Cortical striæ are sometimes noticeable at the periphery of the lens. In the direct ophthalmoscopic examination the maximum opacity will be found at the circumference of the opaque area, and not at the centre. This form is known as *lamellar cataract*.

6. It is very unusual to find cataract first commencing between infancy and puberty; but I have met with a few cases in which the opacity seemed to have begun when the patients were about nine or ten years old. They had been sent to school at the age of seven or eight, and had readily learned to read; but at the end of a year or two their sight began to fail, they became at first short-sighted, and then gradually lost the power of reading any but large type, or of recognising faces across a room.

I have observed two distinct forms of opacity in these cases.

In one form the lens was dotted throughout with minute white points arranged in the course of its fibres. These dots were as small as if pricked-in with the finest needle, and the general effect they produced was that of a very faint haziness in the pupil, only recognisable under concentrated light.

In a second set of cases the opacity was wholly confined to the posterior surface of the lens. In some instances there was one isolated patch in that situation, not exactly in the axis of the lens, but reaching from near that point to its extreme edge. In other cases the whole posterior face was covered with very fine opaque lines, closely set together, and converging from the circumference to the centre, so as to produce the effect of a delicate fibrous membrane of concave form. Encircling the exact centre of this opaque surface was a whitish ring, more dense and earthy in appearance than the rest of the striated surface of which it formed a part.

These opacities, limited to the posterior face of the lens, of course require for their detection far more careful observation than congenital cataract of the ordinary kind, in which the whole nucleus is opaque, and the centre probably marked with a chalky-white patch in the very centre of the pupil.

Congenital cataract, whatever form it may assume, is frequently accompanied by a rhythmical twitching movement of the eyeballs, the effect of irregular action either of the recti or the oblique muscles. This twitching is known by the name of *nystagmus*. It does not, however, invariably accompany congenital cataract, some patients suffering from this affection being entirely free from any irregular muscular action; while, on the other hand, *nystagmus* is met with in many cases of defective sight wholly unattended by any opacity of the lens.

There are certain morbid deposits in the deep tissues of the eyeball which in infants and children may be mistaken for the opacity of cataract. Tubercle and glioma, for instance, in their early stage, are not unfrequently mistaken in this manner by very inexperienced persons, but a careful examination through a well-dilated pupil cannot fail to detect the real nature of the disease. Both tubercle and glioma have a more or less yellow colour, and by a practised observer will be recognised as lying much farther back the hinder surface of the lens. At a certain stage, however, of tubercle in the corpus vitreum and glioma the lens becomes cloudy; and how, it may be asked, is a secondary cataract of this kind to be distinguished from one which is primary, and unconnected with any other affection of the globe? In an eye affected with simple cataract the position of the iris is usually vertical, or nearly so; the pupil is active; the lenticular opacity is regularly striated, and perhaps exhibits also at its centre a white dot. In advanced tubercle and glioma, on the contrary, the anterior chamber is obliterated, the pupil is irregular, dilated, and fixed; the lens has an uniformly cloudy appearance, and sometimes receives from the mass behind it a somewhat yellowish tint. Congenital cataract, too, almost invariably affects both eyes; while glioma almost as invariably occurs in one eye only. Tubercle does, indeed, occasionally affect both, but rarely to the same extent, or at the same time.

In children and also in older persons who have been brought under my notice for congenital cataract, I have been struck with the frequent occurrence of diseased teeth; the incisors and canines being dwarfed, deficient in enamel, discoloured and honey-combed on their anterior surface, and their cutting edge worn away and blunt. I am unable to offer any explanation of this condition of the teeth, which I do not find mentioned by any ophthalmic observer. [Attention has been called recently by several observers to this association; but its exact nature must be regarded as still unsolved.—J. W. H.]

CATARACT IN ADULTS.

Except as a result of injury, cataract is rarely seen to commence between puberty and the middle period of life. Up to the age of forty it is a rare disease, it becomes more common in patients who have passed their fortieth year, but it is after the age of fifty or sixty that we are more especially on the watch for it in patients complaining of failing sight.

Even up to extreme old age cataract usually commences at the circumference of the lens, in the form of opaque strizæ, which gradually advance along the anterior and posterior faces of the lens towards its axis.

About the same time very fine whitish lines may be observed to radiate from the anterior pole of the lens, marking the divisions which exist between the planes

in which its notes are arranged. After the age of sixty a hazy condition of the nucleus is commonly found co-existing with advanced marginal opacity; but even in extreme old age it is far more common, as I have already observed, for cataract to commence at the margin than at the nucleus.

If we trace the rise and progress of cataract in an elderly person, the changes will usually be found to occur in the following order. First, opaque striæ are formed at the extreme edge of the lens, and commonly it is the lower edge which is thus affected. These striæ gradually coalesce into patches, and then spread themselves over the posterior face of the lens, only a few extending a short distance over the anterior face. At this point of development the cataract may remain stationary for a year, or even for several years. Then a farther change takes place, and the whole body of the lens, but especially the nucleus, becomes slightly hazy, but not so as to prevent the posterior radiated opacity from being recognised when properly illuminated. The opaque striæ on the anterior face of the lens gradually advance until their tips appear within the area of the pupil. The haziness of the body of the lens increases until even concentrated light fails to reveal the posterior striæ, and at last only the anterior surface of the lens can be seen. At this stage of cataract, vision is restricted to mere perception of direct light, or of that reflected from white or polished surfaces. Perhaps bright colours may still be recognised.

Up to this point the fibrous structure of the lens can still be traced; but as years go on, its surface becomes more opaque and whiter, in consequence of disintegration of the superficial fibres, and the deposit among them of earthy and fatty material. Occasionally crystals of cholesterine, just within the capsule, may be recognised by their peculiar sparkling appearance.

Fluid cataract; Morgagnian cataract.—The softening process, which begins in the superficial portion of an opaque lens, may go until, in the course of years, the whole mass becomes converted into a thin pulp. The nucleus, for a long time, resists this softening change, and a lens consisting of a firm nucleus, surrounded by a turbid pulp of disintegrated tissue, has received the name of ‘Morgagnian cataract.’

It sometimes happens that this final stage of superficial softening does not occur, and the cataract is then very difficult of detection without optical aids, having a dull brownish appearance like horn.

A very rare form of lenticular opacity is that termed ‘black cataract.’ The name is frequently given to lenses which are only of a dark-brown colour, but absolute blackness is sometimes met with. It must not, however, be supposed that in these cases the blackness of the pupil is like that presented by a healthy eye, in which all the humours are perfectly clear. In the two or three cases of black cataract which I have seen, there was not the slightest doubt as to the existence of a cataract, although the blackness, so remarkable after extraction, was not suspected; for, in each instance, several fine whitish lines could be seen radiating on the anterior surface of the lens, formed, no doubt, by slight earthy deposits just within the capsule.

It should be known that ‘black cataract’ is a popular German expression for amaurosis.

TRAUMATIC CATARACT.

The lens may lose its transparency in consequence of a blow on the eye, although the globe may not be ruptured, or the lens itself displaced from its connections; the mere shock apparently being sometimes sufficient to affect the nutrition of the lens, and induce a gradual opacity of its whole substance. Since, in some such cases, rupture of the capsule can be demonstrated, it probably occurs in all.

Any penetrating wound of the lens is sure to produce cataract, and if the wound in the capsule remains widely open, so as to allow the superficial cells and fibres of the lens to imbibe the aqueous humour, the whole mass gradually becomes disintegrated and absorbed, so that eventually a wounded lens may wholly disappear without any surgical interference. It was a knowledge of this natural process that

first suggested the operation for the cure of cataract by *solution*. It is only in exceptional cases that the whole lens becomes absorbed in consequence of a wound. More commonly it happens that a certain portion of lens-tissue remains enclosed within the capsule, and undergoes fatty change.

Dislocation of the lens into the anterior chamber.—This accident takes place as a result of external violence, such as a blow upon the eyeball or a violent fall. It more frequently happens when the lens has been long in an opaque condition, and its suspensory ligament weakened, or partially detached by disease. The appearance of an opaque lens in the anterior chamber is so peculiar, that the nature of the accident can hardly be mistaken. When the lens is dislocated in a transparent state, its margin presents the appearance of a ring of golden light. Pain and inflammation set in very soon after the occurrence of the accident, and loss of the eye can be averted only by prompt removal of the lens, through a suitable opening in the cornea.

I have already spoken of certain forms of partial displacement of the lens, when treating of the inflammation such accidents give rise to (see the section, 'Traumatic Iritis,' p. 53); and have considered 'subconjunctival dislocation of the lens' in the chapter on Affections of the Sclerotic (p. 48).

Treatment.—Can cataract be cured without an operation? This question will be answered in the affirmative by quacks, who, for their own selfish ends, avail themselves of that shrinking from anything bearing the name of an operation which is a natural instinct in us all, and pretend, by means of liniments, or drops, or the still more scientific-looking galvanic battery, to turn opaque lenses into clear ones.

It would be presumptuous and absurd to pronounce absolutely that no cure for cataract, short of a surgical operation, can ever become possible. But certainly nothing approaching to such a cure has hitherto been discovered.

It must always be remembered that simple opacity of the lens, however far advanced, never deprives a patient of perception of light, provided the retina is sound. Indeed, in the great majority of instances, a patient with no other disease in the eye but an opaque lens, will not only readily perceive the shadow of a hand, or other object, passing between him and the sky, but, with his back to the window, will perceive the light reflected from a sheet of paper, although he may be quite unable to detect the form of the reflecting surface. Many patients, with densely opaque lenses, will, in the same position, recognise well-illuminated coloured surfaces, such as bright red or yellow, or will even discriminate between yellow and white. If, in addition to this perceptive power, the iris maintains its vertical plane, the pupil is round and active, the cornea brilliant, the consistency and movements of the globe perfect, the surgeon may regard the cataract as suitable for operative treatment.

OPERATIONS FOR CATARACT.

These may be arranged under three heads,—*depression, solution, and extraction*,

1. In *depression*, or 'couching,' as it was formerly termed, the lens is thrust from its natural position down into the vitreous tumour behind the iris, in such a manner that, although still within the eye, it may allow the light to pass unimpeded through the pupil to the retina. This method of operating is quite abandoned.

2. The operation by *solution* or *absorption* grew out of that by depression; for it was found that, if, in the attempt to depress the lens, it accidentally became much broken up, the fragments gradually dissolved and disappeared.

3. In *extraction* the lens is lifted bodily out of the eye through a wound in the cornea.

OPERATION BY SOLUTION OR ABSORPTION.

I have said that this operation grew out of that by depression; and it is only surprising that some of the older surgeons, who had been struck by the manner in which fragments of the lens, accidentally detached during their attempts at

depression, became spontaneously absorbed, did not earlier discover that this principle of absorption might be applied to the removal of the whole lens.

When this principle began to be understood, surgeons fell into the mistake of supposing that the more completely the lens was broken up at first, the quicker would absorption go on; and they therefore endeavoured to cut up the whole lens into fragments, by what was termed the operation of *discission*.

The leading principle to be observed in all operations for the solution of a cataract is, not to oppress the eye with more broken-up lens-tissue than the absorbing power of the organ is capable of rapidly removing. If this rule be neglected, the numerous fragments act as so many foreign bodies; inflammation is set up in the iris and cornea, and then all absorption is at once arrested. The conjunctiva and sclerotic become injected; there is pain in and around the eyeball, with intolerance of light and lachrymation; the aqueous humour is turbid, and the epithelial surface of the cornea dull and uneven.

Operation of Infants.—The breaking up of the lens, if carefully performed, is so devoid of danger that it should by no means be deferred on account of the tender age of the child; on the contrary, by operating early there is a greater probability of obviating those twitching movements of the globes (*nystagmus*) which so frequently attend congenital cataract. Of course, if the infant were extremely puny and ailing, affected with diarrhoea, or in any way weakened by temporary derangement of health, the operation should be deferred for a while, until the health has been restored; but it is desirable not to wait until the irritation of teething sets in.

The needle I prefer for most of the operations on the lens has a small lance-shaped head, and the relative proportions of the head and the shaft of the instrument should be exactly such as will allow of the shaft playing with perfect freedom in the aperture which the head has made. If these proportions are not accurately preserved, and the shaft is made larger, with the view of preventing the escape of the aqueous humour, it becomes wedged in the wound, and all movements of the point are difficult and constrained. A needle of a larger size than that used for the ordinary operation on infants is very useful in breaking up the capsular obstructions which remain after the lens-tissue has become absorbed, as the head may be of such a size as to allow of its convex edges being made to cut.

All cataract operations are best performed on patients lying down. Infants are best secured by swathing them from the chin to the feet in a round towel. An assistant steadies the head by placing a hand on each side of it, the lids are kept apart with a spring speculum, and sometimes it becomes necessary for a little fold of the conjunctiva, close to the cornea, to be nipped up in a forceps, so as to steady the eye. If the operator contents himself with using a single needle, he can himself with the other hand use the forceps; but if he prefers a more complete laceration of the lens by the use of two needles at once, which is not advisable, he must of course entrust the forceps to the hands of a second assistant.

Previous to any needle operations for cataract, the pupils should be dilated with a few drops of solution of atropine, applied an hour or so before.

The needle is to be introduced through the cornea¹ close to its junction with the sclerotic, and carried on until its point reaches the centre of the pupil. Then the anterior capsule is to be freely lacerated in various directions, and the body of the lens broken up.

If two needles are used together, the first should be passed in until its point reaches the middle of the pupil, before the second one is introduced through the cornea.

In an infant with congenital cataract both eyes may be operated upon at once; but in an adult the worse eye, if there be any difference, should be operated on first, so as to leave the patient one partially useful eye, while the process of solution, with the temporary loss of sight which it involves, is going on.

¹ I am assuming that all operations for solution of the lens, and for removal of capsule, are to be performed by *keratonyxis*. Formerly the needle was always passed through the sclerotic (*scleromyxis*); but the operation through the cornea, allowing, as it does, the point of the instrument being always kept in view, is evidently to be preferred.

After the operation both eyes should be kept closed by means of a light bandage, or strips of plaster on the eyelids, for twenty-four hours, by which time the little wounds in the cornea will have closed.

If the lens has been effectually broken up, and the infant is in good health, a few weeks will sometimes suffice to insure the absorption of the entire cataract; and the capsule, gradually retracting towards the periphery, will ultimately form a white ring almost or altogether concealed by the iris when the pupil is contracted.

But it is not always possible to effect this complete dispersion of the cataract by a single operation, and the capsule, enclosing between its layers a certain amount of unabsorbed lens-tissue, remains as a chalky-white disk, blocking up the pupil and preventing all useful sight. In such cases two needles must be employed, and the central portion of the opaque membrane torn through to the desired extent; or, in some cases, it may even be necessary to introduce the forceps through an opening made in the cornea, and extract the capsule. This latter proceeding, however, should never be resorted to if a good central opening can be effected by means of the needles only; for, in spite of every precaution, the pupillary edge frequently becomes adherent to the wound made for the introduction of the forceps; or else the traction of the iris, to which the capsule often adheres, causes subsequent distortion and deformity of the pupil, besides its tendency to lacerate the iris and provoke inflammation.

Operation on children and adults.--The cataracts which come before us in children, and in persons under thirty years of age, are very commonly those of the congenital form, which had been overlooked during the period of infancy. For it is rare to meet with instances in which cataract *begins* to be developed in childhood, or in the early years of adult life. The operation for the solution of cataracts of this kind is the same as that I have just described on the infant, with this important exception--that in the older subjects we must take care not to set up irritation in the eye by too extensively breaking up the lens at first; least of all must we be indifferent to the risk attending the accidental displacement of the lens into the anterior chamber, an occurrence which, as I have said, may happen in the infant without any bad results.

In the first operation on an adult, the surgeon should not do more than freely break up the anterior capsule to an extent equal to the area of the pupil when not under the forced dilatation of atropine, and dis-integrate the superficial portion of the lens, without disturbing the nucleus. This may be done with a single needle, the sprung speculum being used or not, according to circumstances. When aided by a skilful assistant, the surgeon may often dispense with the speculum; but it is usually more convenient to employ it, and its use will enable the surgeon to perform the operation alone, if no assistant is at hand.

In using the needle, the surgeon is always to begin to act with the point upon the central portion of the lens; and in all subsequent operations he is to work from the centre.

If, instead of beginning to attack the lens at the centre, the surgeon uses the needle at random, and breaks up the lens at the circumference, he will probably set loose some portions of capsule, which will afterwards wave to and fro in the pupil, and be a most serious impediment to the final success of the case.

After the operation both eyes must be kept closed for twenty-four hours, at the end of which time the needle-wound is usually united, and the aqueous chamber refilled. From the second day it will only be necessary to close the operated eye, and after a few days a shade may be substituted, and then that may be laid aside for a pair of tinted glasses. The day after the operation atropine should be reapplied, and its use continued so long as any sclerotic redness remains, or so long as the swollen and macerated lens threatens to press upon the iris. Day by day the white flocculent lens-tissue continues to pass through the opening in the capsule; and if the pupil is not kept well dilated, so as to make room for the increasing bulk of the lens, the iris will become inflamed, and pain will be set up in the eye.

No absolute rule can be laid down as to how often and at what intervals it will

be necessary to repeat the needle-operation. In exceptional cases I have known a single operation suffice for the total absorption of the lens even in an adult : and in a healthy infant, after completely breaking up the lenses, I have seen both of them wholly absorbed at the end of two months. More commonly, it is necessary in children and young persons to repeat the disintegration of the lens a second time, at an interval of some months after the first operation, and a finishing touch with the needle may subsequently be required thoroughly to clear the pupil from capsule. It is important not to be premature in performing this final operation on the capsule, for during the process of absorption it undergoes so many changes of position by shrinking, that time should be allowed for it to settle into its permanent position before the final laceration of it is made.

It sometimes happens that, either on account of the lens having been too much broken up at once, or in consequence of the absorbing power having been checked by inflammation, the eye becomes oppressed by the displaced fragments of lens ; the sclerotic and cornea then become injected, there is intolerance of light and profuse lacrymation, the iris becomes discoloured, the aqueous humours turbid, the cornea hazy and uneven on its epithelial surface. When these symptoms set in, the eye will be lost by inflammation, unless it be forthwith relieved from the pressure of the swollen lens. The lids being separated with the sprung speculum, and the globe steadied with a forceps, an incision is to be made in the cornea not too close to its margin, lest the iris prolapse, and through this a small scoop or spatula is to be introduced into the anterior chamber. The softer pulpy portion of the lens will then escape along the groove of the scoop, or by the side of the spatula when it is rotated, or it may be sucked out through a tube ; and if this operation has been resorted to in time, an eye which had presented all the phenomena just described may be speedily restored to a healthy state, and that portion of the lens which has been left *in situ* will steadily undergo complete solution.

When a perfectly fluid cataract, or one which has to a very great extent undergone the fluid change, is operated on with the needle, it almost invariably happens that distressing nausea and violent vomiting set in immediately, and in some cases I have known this state of sickness, attended with intense neuralgia, to continue for twenty-four or thirty-six hours. As soon as the capsule is punctured with the needle, a puff of creamy fluid takes place into the anterior chamber, and a farther escape of this fluid conceals the iris from view. If nothing further is done, the distressing sickness is almost sure to set in ; but if the surgeon gently withdraws his needle, and immediately introduces at the same spot a broad cutting-needle, or the point of a cataract-knife, and rotates the blade, the whole of the milky fluid is evacuated, and the sickness is wholly or to a great extent averted. The nausea is best combated by allowing the patient frequently to swallow small fragments of ice ; and the neuralgia in the ophthalmic division of the fifth nerve will probably yield to the application of chloroform liniment, applied by means of lint to the forehead and temple.

Operations on opaque capsule.—It sometimes happens that, in breaking up a cataract with the needle, the capsule is so effectually lacerated, that it retracts sufficiently to leave the area of the pupil unobstructed ; but these are exceptional cases, and usually, after the lens-tissue has been wholly absorbed, there remain some portions of opaque capsule, which must be removed before the cure can be considered complete.

Capsular obstructions are likewise met with after extraction of the lens ; and it seems desirable, therefore, to defer the consideration of them until the operations of extraction have been described.

OPERATION OF EXTRACTION.

The solution and absorption of a cataract in an old person is an extremely slow process, partly on account of the density and impermeability of the nucleus of the lens, and partly in consequence of the diminished activity in the interchange of

material which characterises the tissues of the body in old age, so that discission is now never practised in old people, in whom a little more rapid removal of the opaque lens, therefore, becomes desirable; and the surgeon will find it preferable, in patients above thirty years old, to have recourse to extraction.

We may group the various forms of extraction under the heads: *Flap-Extraction*, *Peripheral-linear-Extraction*, and *Scoop-Extraction*.

The objects to be kept in view are the following:—

To make a crescentic opening in the cornea sufficiently large to afford an easy exit to the lens. Freely to lacerate the anterior capsule, so as to allow of the lens readily slipping through the rent when pressure is made on the globe. Lastly, to apply this pressure in such a manner that the lens may be made slowly to turn on its transverse axis, and thus to present its upper margin first at the pupil, and then at the corneal wound.

The pressure must be regulated with a nicety which is hardly possible unless the operator has the eyeball under his sole management. The best position for the patient, therefore, is to lie upon a high couch, with his head alone slightly raised.

The patient being placed in the manner described, the surgeon, standing or sitting behind him, raises the upper lid, placing his fingers against the very edge of the tarsus, so as to prevent eversion. An assistant draws the lower lid downwards, and keeps it fixed by making pressure against the malar bone. He must take especial care to do this, and not in the slightest degree to press upon the eyeball. The surgeon may control its movements by allowing the tip of one finger lightly to touch the sclerotic just above the cornea, while the other rests, as lightly, against the inner side of the globe. To do this safely requires the greatest tact and care; for, as soon as the knife has transfixed both sides of the cornea, all pressure must cease, and it ought at no time to be greater than will just suffice to enable the surgeon to make his puncture and counter-puncture with certainty. Firm pressure, kept up till the section is completed, will almost inevitably cause the lens to be violently ejected, with a gush of vitreous humour. Instead of this, it has now become customary to separate the eyelids with a speculum, and to steady and fix the eyeball by seizing with a forceps the conjunctiva and underlying fuscina close to the cornea, near the point of counter-puncture.

The point of the knife is to be introduced on the equator of the cornea, a short distance in front of its junction with the sclerotic, carried steadily across the anterior chamber, and brought out at the corresponding spot near the inner margin of the cornea. During this thrust the edge is directed towards the upper margin of the cornea, so that, when the section is completed, a semi-lunar flap results.

The surgeon must take care to give the knife a steady onward pressure, so that the blade may constantly fill up the wound it is making. The utmost care, however, will not always avail to prevent the loss of aqueous humour; for so ready is the fluid to spurt out, that, if the sides of the knife be unevenly ground, sufficient space may exist between the blade and the edges of the wound to allow of the escape.

When this has occurred, if the iris should fairly come over the edge of the knife, the surgeon may disengage it by drawing the point of one finger over the cornea, from below upwards, and then making a little pressure directly backwards. In this way the iris may be made to slip back behind the edge, and by keeping up careful pressure until the section is nearly completed, the iris may be prevented from coming forward again.

The operator may find it impossible wholly to disengage the iris from the knife, and a portion of the upper margin of the pupil may be cut away. This of course causes a slight bleeding into the anterior chamber, which obscures a view of the parts during the next stage of the operation, but the lens usually escapes readily through the artificially enlarged pupil, and, except the deformity, no permanent bad result necessarily follows the accident. Sometimes, however, it happens that a *fold* of the iris is cut through, so that there results a hole in the iris just above the true

pupil. When this occurs, the surgeon must at once divide the strip of iris between the two apertures, so as to lay them into one before he proceeds to lacerate the capsule.

As soon as the corneal flap has been completed, if the speculum is not employed, and the patient is not under the influence of an anæsthetic, the upper lid is allowed gently to fall, care being taken that it does not catch against the edge of the flap and evert it; and the surgeon proceeds to the second stage of the operation—the division of the anterior capsule.

After a short pause, he again carefully raises the upper lid, without making pressure on the globe, and surveys the wound. If he has made it too small, he must at once enlarge it, by passing a short, narrow, blunt-ended knife, or the blade of a pair of scissors, under the flap, to the outer angle of the wound, and carefully dividing the cornea close along its margin, in a downward direction.

No difficulty should deter the surgeon from making the wound sufficiently large before attempting to press out the lens; for if, while the opening in the cornea is too small, pressure be made on the globe, the hyaloid membrane will probably give way, and allow a portion of the vitreous humour to escape; and immediately the lens, instead of presenting itself at the section, sinks down into the space left by the lost humour.

When this occurs, the surgeon must at once desist from all pressure on the globe and pass in a fine sharp hook through the now gaping wound, and through the pupil, to the hinder surface of the lens, which must be drawn out as quickly and as lightly as possible. Sometimes it is better to pass in a scoop instead of the hook; but, whichever instrument is employed, it must be placed *behind* the lens, which is to be kept well pressed against the cornea, otherwise it will be driven still deeper into the vitreous humour.

If the surgeon has satisfied himself that the corneal wound is sufficiently large to allow of the easy exit of the lens—and for this purpose it ought to involve nearly half the circumference of the cornea—he next proceeds to lacerate the anterior capsule. The cystitome is slipped under the corneal flap, care being taken not to entangle the point in the iris; and when its curve is fairly in the pupil, the handle is rotated so as to bring its point against the capsule.

In tearing through the capsule, the surgeon should take care that the rents extend quite across the area of the pupil. This laceration of the capsule requires a careful eye and a light hand, otherwise the lens itself may be displaced.

The cystitome having been withdrawn, with due care against entangling it in the iris, the surgeon proceeds to the last act of the operation—the removal of the lens.

It is a fatal error to suppose that this removal is to be effected by main force; that the eye may be squeezed in any direction, if only it is squeezed hard enough. The real object of pressure is to make the lens first turn on its transverse axis, so that its upper edge may become tilted a little forwards. To effect this the convexity of the scoop is laid against the lower lid—which the assistant is not to touch during this stage of the operation—and gentle pressure is to be applied through the lid against the sclerotic, or directly on the sclerotic if the eyelids are held apart with a speculum a little beneath the lower margin of the cornea. With the forefinger of the hand which holds the upper lid, similar gentle pressure is made on the upper part of the globe, just above the section; and then, by a carefully-regulated alternating pressure on these two points, the lens is made slowly to turn and present its upper edge at the pupil. Coming in contact with the cornea, the edge of the lens is guided upwards, and begins to protrude at the corneal wound. It is evident that as soon as the widest part of the lens has passed through the pupil, the rest will be inclined rapidly to follow; and therefore, if the surgeon does not moderate his pressure, the lens will suddenly start forward, and will very probably be followed by a gush of vitreous humour. According to the size of the corneal wound, and the degree of superficial softening the cataract has undergone, will be the amount of soft matter the lens will leave behind in passing out of the eye. A small lens will perhaps escape entire through a large wound; while if the wound be small, and the lens

bulky and much softened on its surface, a considerable quantity of lens-matter will remain in the pupil and about the lips of the wound.

Quick union of the corneal wound, upon which so much of the success of the operation depends, cannot take place if any foreign matter be allowed to remain between its edges; all soft lens-matter, therefore, which may be sticking there, must be carefully removed with the scoop. The iris, which very frequently protrudes, can be best returned to its position by means of the small spatula. It is unwise to dip again and again into the pupil with the scoop for the purpose of removing every portion of soft lens-matter. The capsule cannot be removed by such means; and it is to this that the fragments very often adhere, and a too free use of the scoop is very likely to rupture the hyaloid membrane, and cause a gush of vitreous humour.

Provided the lips of the wound are in perfect apposition, and the iris in its proper place—which may be known by the central position of the pupil—the capsule, and any very small portions of entangled lens matter, may safely be left for future removal, after the wound is healed and all irritation passed away.

When a gush of vitreous humour takes place at the moment the lens passes, the surgeon must immediately close down the upper lid, lifting it over the wound by the eyelashes, so as to prevent the edge of the tarsus catching against the projecting flap of cornea. The lids must at once be closed with strips of plaster and a bandage.

Although cases in which a small quantity of vitreous humour has been lost may ultimately do well, a deformity of the pupil always remains. It is large and drawn up towards the wound, and the iris forming the upper margin of the pupil retracts, so as to disappear altogether.

In the foregoing description of the operation by extraction, I have noticed some of the accidents that are liable to occur: but there remains to be noticed one more dangerous than all others, namely, *hæmorrhage into the vitreous chamber*.

Although the corneal section may have been perfectly well made, and every due precaution taken, it sometimes happens that a gush of vitreous humour, usually of watery consistence, occurs at the moment the lens escapes through the wound. Within a few seconds, or at the end of a minute or two, the patient complains of severe pain in the eye, and blood appears oozing from between the lids. This oozing does not take place until the whole cavity of the eyeball has become filled with blood. In some instances, the hæmorrhage sets in several hours after the operation. Some diseased condition of the deep-seated tissues must exist in all these cases—a change of structure in the vessels of the choroid, with or without serous effusion between it and the retina. I need hardly say that, in all these instances of hæmorrhage, sight is utterly lost.

A similar hæmorrhage sometimes follows the removal of staphylomatous projections of the globe. As soon as the prominent portion of the staphyloma has been cut off, the pent-up aqueous fluid and serum, and the diffuent vitreous humour, gush out at the wound; and this sudden removal of support from the enlarged choroidal vessels causes them to give way. In such cases, I have found the whole retina enveloping the large clot which had been forced out of the eyeball; a proof that the blood which had detached the retina must have had its source behind that structure, namely, from the vessels of the choroid.¹

AFTER TREATMENT OF CASES OF EXTRACTION.

The prevalent belief that all operations for cataract are likely to be followed by 'inflammation,' and that the great aim of the surgeon is to keep this down, is of course unqualified in the popular mind by any definite notion as to the nature of this 'inflammation,' why it arises, or what parts of the eye it involves; and many members of the profession, when commencing the study of eye-diseases, have equally vague conceptions of the subject. Let us, then, examine a little into what takes place in an eye after flap-extraction of cataract.

¹ I published two cases of this kind in the *Lancet*, 1846, p. 623.

The cornea has been divided, by a clean cut, to the extent of half its circumference; the aqueous fluid has escaped: the lens has been gently squeezed through the pupil; the iris is in contact with the hinder surface of the cornea, the cut edges of which are in exact apposition; the concave surface of the upper lid lies against the wound, and affords it support.

Within a few hours—provided the nutrition of the patient's body is in a healthy state—adhesion takes place between the cut edges of the cornea. As this adhesion becomes firm, the aqueous humour is retained; it once more fills the anterior chamber, and defends the iris from being pressed against the cornea. The slight irritation to which the iris had been subjected, by the passage of the lens through the pupil, passes off, and within a period longer or shorter, according to the constitution of the patient, the extra quantity of blood, which had been affording reparative material to unite the wound, ceases to be sent thither, and the cure is completed.

If the iris is entangled in the wound, a mechanical obstacle to quick union is thereby established, and union must take place by a slower process, effused lymph agglutinating the iris to the cut edges of the cornea, and then gradually drawing them together. If vitreous humour has escaped through the wound, its edges will be kept asunder for some time, but will eventually unite by adhesion.

The pain which not unfrequently sets in a few hours after an extraction is commonly of a neuralgic kind. The patient's nervous system has been excited by anxiety about the operation itself, or its result. Bleeding is sure to increase this neuralgia; while a due supply of digestible food, a small quantity of stimulus, or a narcotic, will at once arrest the neuralgia and prevent its recurrence.

Extraction of cataract is an operation performed on those who are past the middle period of life, and one naturally expects to find among them many of those conditions of feebleness and impaired function which are incident to old age. No doubt cases occur of an opposite kind, in which the patients are plethoric, over-fed, over-stimulated with alcohol. They require to be 'toned down,' and their circulation brought into a more healthy state, which should be done by regulating their plan of living for several months *before* the operation is performed.

As soon as an operation of extraction has been completed, and the surgeon has satisfied himself that the flap is in a proper position, he should at once close the eye, without permitting any such trials of the patient's sight as may safely be made *after* the removal of opaque capsule, or the formation of an artificial pupil.

A little square of linen is laid upon the closed lids of both eyes, and over this a little pile of cotton-wool, and the whole is then fastened down with a knitted bandage. Some surgeons also apply strips of plaster across the lids.

For some hours after the operation the patient should remain on the couch, comfortably supported with pillows. When in bed the best position is on the back; but this is by no means to be insisted on if it becomes irksome, or makes the patient wakeful. That position is the best which is the most comfortable, and likely to induce sleep.

A narcotic is sometimes needed on the first night; and in some persons, especially those accustomed to opiates, it may require to be repeated for several nights in succession; but such cases form the exception, not the rule. Loss of appetite is so apt to follow the use of these drugs, that they should never be given without manifest necessity. I always prefer tincture of hyoscyamus to opium, as being far less likely to cause discomfort the next day or to confine the bowels.

The patient is of course to be thoroughly waited upon, so as to be spared every unnecessary movement or exertion. Tapes passed round the wrists and attached to the waist are a useful check upon sudden movement of the hands during sleep.

A moderate dose of opening medicine, given a day or two before the operation, will obviate the necessity for teasing the patient with purgatives during the first few days succeeding it. Old and feeble persons, especially those with any heart-disease, are sometimes seriously prostrated by being purged on the second or third day after the operation, just when it is so important that the healing process should be steadily advancing.

As regards diet, patients should not be deterred from taking a nutritious meal a suitable time before the operation; and a moderate quantity of easily-digested animal food should be given on each following day. In respect of stimulants, it is impossible to lay down any absolute rule. Those accustomed to take wine, beer, or spirits, must by no means be wholly debarred from them at a time when the nutrient power of the body is called upon to form new material for repairing a breach of surface. In short, the surgeon's object must be carefully to regulate both food and stimulants according to the patient's previous habits; neither keeping him too high nor too low, but as near as possible up to the ordinary level of healthy vigour.

The daily cleansing of the lids requires caution. The lower lid and cheek are to be cleansed with warm water, but the upper lid is on no account to be touched, for under its shelter lies the corneal wound, sudden pressure on which would induce great suffering, and might even cause the slightly-formed adhesion of the flap to give way.

The progress of the wound towards healing is to be judged of by the condition of the lid, and the quality of the secretion. If the patient complains only of an occasional pricking, or a sensation of grit; and if this can be traced to the slight involuntary movements of the wound against the lid; if this uneasiness subsides day by day; if the secretion consists of tears alone, or is mixed with a little of the natural conjunctival mucus; and if the skin of the upper eyelid retains its healthy appearance, and is free from redness and swelling—the surgeon may entertain the best hopes that a good union is going on.

An increased feeling of grit in the eye, coming on after the lapse of three or four days, and perhaps attended with neuralgia, would lead the surgeon to suspect that the section had yielded, and that *prolapsus iridis* had occurred.

The most unfavourable sign is a bright redness and a swelling of the upper lid, which sometimes appear on the second or third day after the operation, attended with a yellow puriform discharge. These appearances are commonly ushered in by a restless night, with headache and considerable depression both of body and mind. When the lid is raised, the ocular conjunctiva is found injected, and so oedematous that it overlaps the corneal margin (*chemosis*). The cornea itself is throughout yellow and opaque, so that no trace of iris can be discerned through it; the wound is gaping, and filled with bulging iris. Eventually the whole cornea softens, the flap sloughs, and the eyeball shrinks.

I have now and then seen this hopeless state of things come on after an operation which had been perfectly well performed, and when the surgeon had every reason to expect a most successful result. In such cases there has probably been some degeneration of tissue in the vessels supplying the globe, and a weak condition of the heart itself.

The time that should be allowed to elapse after the operation, before the eye is examined, may vary according to circumstances. In a healthy patient, when there has been no pain in the eye, or other bad symptom, the wound may be found perfectly united as early as the third day after the operation. But, as a rule, the fourth day is quite soon enough for an examination; and whenever there has been any loss of vitreous humour, so that the healing process has been retarded, the fifth will be the earliest day on which the eye can be prudently exposed. Indeed, in an old or feeble person, a wound which on the fourth day is going on well, will be all the better for another day of rest; and it often happens that a premature exposure sets up irritation, and, if the union be not firm, favours the subsequent yielding of the wound and prolapse of the iris.

If redness of the upper lid, attended with puriform discharge, comes on within the first two or three days, the surgeon should examine the eye just so far as to obtain a view of the lower part of the cornea, and ascertain whether it is becoming infiltrated with pus: and this may be done without exposing the wound itself.

It would be impossible to detail all the appearances which an eye may present when first examined after the operation; but it may be useful to describe some of the leading points which present themselves, both in favourable and in unfavourable cases.

1. The cornea may be transparent, with the exception of a little hazy line along the edge of the wound; the aqueous humour may have been resecreted, and the plane of the iris vertical; the pupil being either clear and black, or filled with a flocculent mass of capsule and lens-matter, accordingly as the lens has come out clean, through a large wound, or has rubbed off some of its soft cortical substance in passing through a small one. Vision may extend to the recognition of large objects, such as the fingers of a hand; or, in consequence of the obstruction still remaining in the pupil, may be limited to mere perception of direct or reflected light. Some little redness of the sclerotic and conjunctiva will of course be present in every case, an additional supply of blood having been sent to repair the corneal wound.

The appearances above described are most satisfactory, and would encourage the surgeon to look forward to a successful result.

2. The eye may present all the foregoing appearances, with the exception of the iris being in contact with the hinder surface of the cornea. This absence of anterior chamber arises from one or other of the following causes; either the wound, although sufficiently united to keep the cornea in its proper curve, has not become so consolidated as to be perfectly water-tight, and the aqueous humour therefore escapes as fast as it is formed; or else this fluid, which seems to be chiefly secreted in the posterior aqueous chamber, may be so pent up there by the lens matter filling the pupil, as to thrust the whole iris forwards against the cornea. In the former case, by keeping the eye closed for two or three days longer, and giving the patient a little more stimulus or tonic, the wound will become consolidated. In the other case, the iris will slowly recede as the lens-matter in the pupil becomes absorbed, but perhaps will not quite resume its vertical position until the capsule at a later period shall have been broken through with a needle.

It occasionally happens that, although the corneal wound, when examined on the fourth or fifth day, appears well united, it subsequently gives way a little at some point, and allows a small portion of the iris to protrude, so as to cause slight displacement of the pupil.

3. The eye may be found in the following state: the cornea clear, the section gaping, and blocked up with iris, the latter having prolapsed into the wound, after being adjusted at the operation, and no union between the two structures having occurred in consequence of the feeble condition of the patient. In these cases the parts on the fourth day after the operation may appear almost as if the wound had been just inflicted. Chronic inflammation is sure to be set up, and is often attended with neuralgia. In non-union of this kind, it is sometimes good practice to keep the eye uninterruptedly closed for five or six days after the first examination, provided the healthy appearance of the lids, and the absence of puriform secretion, give assurance that the healing process is advancing.

4. Still more unfavourable than the appearances above described are the following: in addition to a gaping section and prolapsus iridis, a cornea hazy throughout, so that the iris cannot be clearly discerned; the edges of the wound thickened, opaque, and creamy-looking; the sub-conjunctival tissue infiltrated with serum, and the conjunctiva itself reddened and elevated (*chemosis*).

These local changes have usually been ushered in with pain in the eye and head, restlessness, and depression. Extreme care is necessary to treat a patient under such circumstances. Narcotics will probably be required at night; of these *hyoscyamus* is the best, and bark and ammonia are almost sure to render good service in keeping up the appetite and restore vigour to the flagging circulation. The diet will require the most careful management, so as to insure a sufficiency of nourishment being taken without oppressing the stomach; above all, the regulation of the supply of stimulants—wine or beer—will demand much judgment on the part of the surgeon, so that the patient's powers may be raised and sustained, without causing irritability and subsequent depression. But it will sometimes happen, in spite of care and skill, that such cases as these will terminate in closure of the pupil, with wasting and softening of the whole globe.

Although it is so important, after the operation of extraction, to defend the

patient from strong light for several days, there is no necessity for closing shutters and drawing curtains closely round the bed, if the patient's eyes have been bandaged in the manner I have described. Very moderate shading of the room is then sufficient, and thorough ventilation is most beneficial; for due aeration of the patient's blood is essential to the healing process.

Prolapsus iridis.—If the corneal section, instead of uniting by adhesion, has undergone that slower process of closure which takes place when a portion of iris is interposed between the edges of the wound, the *prolapsus* continues for some time to be a source of irritation. It should not, however, be too hastily interfered with; for, in healthy subjects, it usually wastes and flattens down by slow degrees. Sometimes, however, instead of diminishing in this manner, it becomes distended into a little vesicle, in consequence of the accumulation of aqueous humour behind it. If the prolapsus fills up nearly the whole extent of the wound, the corneal flap may be tilted forward in such a manner as to form an obtuse angle with the lower portion, the base of the flap being marked by a transverse crease, extending quite across the cornea from one angle of the wound to the other. As the process of contraction in the prolapsed iris goes on, the edges of the corneal wound are gradually drawn together, the transverse crease disappears, and the natural curve of the cornea is eventually restored.

If, however, instead of diminishing, the prolapsus remains as a large and prominent vesicular projection several weeks after the operation, means must be taken to induce it to contract. In many cases it is sufficient to puncture it with a broad needle. The eye must then be kept closed for a day or two. Should the prominence reappear, it had better be snipped off and the eyelids closed with a compress.

Fistulous wound.—If a case be not well watched for several months after the operation of extraction, the wound may become fistulous. This is an extremely rare occurrence; so rare, indeed, as to be unnoticed by most of the authors on ophthalmic surgery.

These fistulae of the cornea are likely to be overlooked, on account of their extreme minuteness; for their aperture is sometimes no larger than the section of a human hair, and the quantity of fluid oozing out is small in proportion. The fistula of course allows a constant escape of aqueous humour, and the anterior chamber becomes obliterated, the iris lying in contact with the cornea. This drain of aqueous humour, if unchecked, seems to exert some peculiarly exhausting influence upon the eye, for in all the cases I have seen in which fistulae of the cornea had existed for several years, all useful vision had become extinct.

There are certain points connected with the operation of flap extraction which may seem to have required notice before the operation itself was described; but it appeared preferable to reserve them for later consideration, because they can be properly appreciated by those only who have already made themselves acquainted with the details of the operation.

Inasmuch as extraction is performed upon persons more or less aged, it must often happen that the constitution of such patients has been damaged by various forms of acute or chronic disease before they come under our care as the subjects of cataract; so that we cannot expect to find them by any means in as favourable a condition for undergoing an operation as those whom we are in the habit of treating for many other surgical affections. There are, however, certain conditions which would either wholly contra-indicate extraction of cataract, or would cause us to undertake the operation only after the most careful preliminary examination, and unusual precautions against the more pressing difficulties of the case.

1. Extensive heart-disease is of all complications the most unfavourable; for, by enfeebling the supply of blood to the peripheral tissues of the body, it lessens the probability of a quick union of the corneal wound.

2. Violent cough, if occurring in suffocative paroxysms, would also greatly imperil the success of the operation: partly by the unavoidable restlessness and frequent

change of posture, and partly by the straining and shaking of the eye, which may disturb the wound, and induce prolapsus of the iris.

3. Fat and flabby persons have much less reparative power than those who are thin. Dry and wrinkled, but still vigorous old people—such as are popularly termed ‘wiry’—are of all others the best adapted to undergo extraction.

4. Mere old age does not contra-indicate extraction; for one occasionally meets with persons of advanced years whose bodily functions are performed with surprising regularity. Commonly, however, the reparative power of the cornea is impaired after seventy.

5. If cataract is equally advanced in both eyes, and both appear equally well suited for operation, ought we to extract both lenses at one sitting? On this question much difference of opinion exists. My own judgment is decidedly in favour of operating on one eye only at a time. We learn much by watching the progress of a case after operation, and often see how, by this or that precaution, or course of treatment, a disfigurement or a bad result might have been avoided. We operate, for instance, on a depressible patient during very hot weather, and find him utterly overcome and prostrated by it, perhaps to such an extent as to induce non-union of the wound, or even partial slough of the cornea. Were this to occur after we had operated on one eye only, we should learn experience by the result, and take care to select a cooler season of the year for operating on the other eye.

Or our patient may have deceived us as to his previous habits. He may for years have been accustomed to take large quantities of stimulants, and our first operation may have failed because we had not kept up his reparative powers sufficiently by artificial aids. Having learned the truth, too late to save the first eye, we might be able, by adopting a different plan of after-treatment, to save the second.

Without unnecessarily multiplying illustrations, I may say that by operating on one eye at a time we secure to ourselves the advantage of making our first operation a means of invaluable instruction with respect to the second, while, at the same time, the effort of nature in repairing a single corneal wound is of course less than is required for the repair of a second wound of equal extent.

6. Ought we to operate when cataract is fully formed in one eye, while the other is either free from cataract, or only slightly impaired by its existence in an early stage?

Exceptional circumstances may make it desirable in such a case to operate on the cataractuous eye; but in the great majority of cases it will be proper to wait until cataract is fully established in the other. Of course, after the extraction of the crystalline lens, a convex glass becomes necessary, to compensate for that portion of the optical apparatus of the organ which has been taken away; and it is almost, if not quite, impossible so to adjust any mechanical aids as to make the operated and the unoperated eye work well together. Each eye, taken separately, may be good; but there is a want of harmony between them which can never be reconciled.

7. The last question to be considered is, whether any particular time of the year is to be preferred for the performance of extraction? As far as the mere operation itself is concerned, I know of no period being positively contra-indicated, except the extremes of hot and cold weather. Severe cold acts unfavourably on old people by retarding the circulation of blood in their capillaries; while extreme heat enfeebles the action of the heart, especially when it happens—as is so common in old age—that some organic change has already taken place in it. The only time which I systematically avoid for performing extraction is during the sultry weather which sometimes visits us in July and August.

But one has to consider not merely the operation itself; the period of complete repair and convalescence is equally important. It is of the utmost consequence that a patient who has gone through the confinement and the mental anxiety inseparable from so important an operation as that for cataract, should at the earliest possible period enjoy the invigorating influence of change of air; and nothing tends so much to prolong that condition of chronic ophthalmia, which sometimes follows extraction,

as too long a confinement to the sick-room. A few days of careful exposure to the fresh air during genial weather equally improves the eye and the patient's general health. It is, therefore, of importance so to time the operation that the period of convalescence may coincide with the finer season of the year; and this can only be done by choosing the spring and early summer for the operation: April, May, and June are, therefore, the best months to select for extraction, although the later summer months may be chosen, provided the weather be not sultry and oppressive.

LINEAR EXTRACTION.

This operation is a modification of that invented by Gibson.¹ He advised that soft cataracts should be freely broken up with a needle, and that after inflammation had subsided—in three or four weeks—a small incision should be made in the cornea, and the broken-up lens removed with a scoop. As the true principles which regulate absorption of a cataract in its natural position, when its tissue has been carefully broken into with a needle, became better understood, Gibson's operation fell into disuse. The fallacy of his procedure was revealed by the words 'after inflammation had subsided.' If by breaking up all the lens at once inflammation was set up, the proper practice would have been at once to evacuate the lens-matter which was the cause of the inflammation. Either do this, or adopt the slower, but safe course of only disintegrating the lens sufficiently to induce the absorbing process, without throwing the bulk of it into the anterior chamber all at once.

The late A. v. Graefe modified Gibson's operation² in the following manner. After having dilated the pupil with atropine, he made a straight vertical incision, two, two and a half, or three lines long, through the cornea, not at its margin, but about a line nearer its centre. Such a 'linear' wound, he remarked, would heal more readily than a flap wound, and would involve less risk of *prolapsus iridis*. But, on the other hand, a rectilinear wound does not gape, and it therefore requires more manipulation to evacuate the pulpy lens-matter. Through the wound he passed in a small fleam-shaped cystitome, and with it broke up the capsule and the substance of the softened lens. Then a scoop was introduced into the midst of the pulpy mass, the wound was made to gape, by pressing the instrument against its edge, and the broken-up lens-matter escaped along the groove.

'Linear extraction' was not proposed by Graefe as a substitute for the older flap operation. He considered it to be specially suitable to cases of fluid lens, the corneal wound being made about two lines long; or when the lens was almost of a pulpy consistence, rather a longer incision being then required. When the lens had returned the normal consistence of adult life, and still more when in old age it had acquired increased hardness, he considered the operation contra-indicated.

In consequence of these limitations of the operation being disregarded, and its being applied to cases of firm cataract, it fell into discredit.

Removal of cataract by suction.—In 1847 Laugier announced a quick and easy method of removing softened cataracts by suction; 'par aspiration,' as he termed it. He thrust a sort of cannula through the sclerotic into the substance of the lens, and then professed to draw out the contents of the capsule by means of a piston. A less dangerous mode of operating was soon afterwards proposed by Blanchet, who employed a cannula and syringe somewhat similar to Laugier's, but with the much safer modification of introducing the cannula through a wound in the cornea. Suction fell into disuse, until it was revived, under a much more delicate and skilful form, by Teale,³ in 1863. With two needles he tore up the capsule; then made a small wound in the cornea, through which he introduced a flattened cannula, or curette, into the body of the lens. A flexible tube attached to the curette terminated at the other end in a mouth-piece, and the operator gently sucked out the softened

¹ *Practical Observations on an Artificial Pupil, with remarks on the Extraction of Soft Cataracts*, 1811.

² *Archiv für Ophthalmologie*, Bd. ii. S. 217, 1855.

³ *Ophthalmic Hospital Reports*, vol. iv. p. 197.

lens-matter. A syringe has sometimes been substituted for the tube. The reader will at once see that this must needs be a very delicate proceeding, and that if a too great power of suction be employed, serious mischief to various tissues of the eye may ensue.

However applicable to the cataracts of adults suction may prove to be, it is quite uncalled for in the congenital cataracts of infants, except when time is a great object, and in the course of dissection the lens swells much and provokes inflammation. As I have already observed (p. 89) a lens freely broken up, and even to a considerable extent displaced into the anterior chamber, does not at that early age set up irritation; and in a few months every trace becomes absorbed and disappears.

SCOOP EXTRACTION.

In many cases of cataract it is impossible to determine absolutely to what extent the softening process may have extended, and what amount of hard nucleus may still remain. It often happened, therefore, that the surgeon who had commenced the rectilinear operation in the belief that the whole lens was pulpy, found himself embarrassed by a firm nucleus of considerable size. The removal of this mass required so much mechanical interference, that the iris became bruised and injured, and also fragments of lens might remain behind the iris and set up the most serious irritation. These and other complications seem to have led Graefe to devise a mode of operation whereby the iris might be saved from injurious pressure, and at the same time additional room might be made for removing even a firm nucleus through a corneal wound smaller than that made in an ordinary flap extraction. The result of these attempts was the operation of scoop extraction.

And here I would observe that, whatever may be the final verdict which, after more extended experience, may await the operation of scoop extraction, its invention is wholly due to Graefe, who to a great degree has been deprived of the merit of having originated it.¹

There is no doubt that one of the chief causes of failure after a well performed flap extraction, is the occurrence of prolapsus iridis, and by the iridectomy proposed by Graefe all possibility of this was of course avoided. At the same time ample room was made for the removal of a large and solid nucleus, and through a less gaping wound than the crescentic incision of flap extraction. By the use of a scoop to draw out the nucleus, all pressure on the globe was rendered unnecessary.

Scoop extraction seems most suitable to those cataracts which are in an intermediate condition between the semi-fluid state which admits of a complete evacuation through a rectilinear incision, and the hardness of those in which little or no superficial change has taken place.

From the diminished risk of escape of vitreous humour, during scoop extraction, in consequence of the smaller corneal wound and the absence of pressure on the globe, the vomiting which so often follows the use of chloroform is of less consequence than in flap extraction; and therefore it may be administered in operations with the scoop, although in very quiet patients it may not be necessary. •

The lids being well separated with a spring speculum, the surgeon fixes the globe, by nipping up a fold of ocular conjunctiva below the cornea. He then passes in a lance-knife at the upper edge of the cornea close to its junction with the sclerotic.² Next a forceps is passed in at the wound, a portion of iris seized, drawn out, and cut off. The cystitome is then used to lacerate the anterior capsule, which should be done to the full extent of the now enlarged pupil. Lastly, the scoop is insinuated behind the upper edge of the lens, and carried on until the end of the instrument has passed just beyond the lower edge. The entire lens is then gently drawn out.

¹ The operation was very fully described by him in the fifth volume of the *Archiv für Ophthalmologie*, pp. 158-173, 1856.

² In his first description of the operation, Graefe advised that the cornea should be incised at its outer edge; but the deformity, and other disadvantages resulting from an over-large and misshapen pupil, are better obviated by making the incision upwards.

This sliding of the scoop behind the lens is the act of the operation which requires the most care, for by rudely thrusting the instrument too much backwards, its point might be made to break through into the vitreous humour. The surgeon must bear in mind the convexity of the hinder face of the lens, and give to the scoop a corresponding curved sweep.

It will depend upon the degree of softening which the surface of the lens has undergone, how much pulpy lens-matter will remain behind after the nucleus has been drawn out. As much of this pulp as can be got away without risk of breaking into the vitreous humour should be removed; but provided no solid nodules remain, the surgeon need not be over-anxious to get out every particle of soft matter. Each re-introduction of the scoop tends in some degree to irritate the edges of the corneal wound, and there is always the risk I have adverted to of breaking through with the instrument into the vitreous humour. The corneal incision being left clear of any lens-matter, the bandage may be applied over both eyes, as after flap extraction.

On examining the eye for the first time, the surgeon will sometimes find that the whole, or nearly the whole, of the enlarged pupil is filled with a flocculent or pulpy mass; but provided the wound be united, and the cornea clear, this obstruction of the pupil need not disquiet him. All will in time become absorbed, or if any considerable quantity should eventually remain, it may be cleared away by the aid of two needles, used in the manner hereafter described.

In most cases the softened periphery of the lens is sufficiently opaque to be readily seen at the time of the operation; but it is sometimes so nearly transparent as to be very difficult of detection, and it only becomes opaque and strikingly visible two or three days afterwards.

Although, from what I have said, it will be seen that the two great accidents which attend or follow flap extraction, loss of vitreous humour and prolapsus iridis, may be evaded by a carefully performed scoop operation, let not the reader suppose that the latter mode is to be regarded as 'extraction made easy,' or that success is always to be looked for. Cases occur in which, after the most careful scoop extraction, infiltration and softening of the cornea take place; or a more chronic form of irritation ends in permanent opacity of a large portion.

Graefe's scoop operation with iridectomy has undergone several modifications. One consists in first performing iridectomy, then waiting till the corneal wound is healed, and the anterior chamber restored; and then, by a second operation, removing the cataract with the scoop.

Another modification is as follows. A crescentic incision of the cornea is made, and the lens removed, as in ordinary flap extraction. A forceps being then passed in at the wound, the iris is seized, drawn out, and cut off, just as in the operation for glaucoma; the whole being done while the patient is under chloroform.¹

PERIPHERAL LINEAR EXTRACTION; MODIFIED FLAP EXTRACTION.

This operation, the latest form of extraction that emanated from the fertile invention of the late A. von Graefe, or one of its many modifications, is now generally preferred to the older flap extraction just described. It is frequently called 'modified linear extraction;' but, inasmuch as a considerable incision is made in the cornea, and the lens is brought out entire, by being pressed through the wound, the procedure certainly bears more resemblance to a flap extraction than either to the 'linear' or its 'scoop' modification.

The patient is brought under the influence of chloroform; the lids are separated with a speculum; and the eyeball is steadied by nipping up with a forceps a fold of conjunctiva below the cornea. The knife, which is long and very narrow, is made to pierce the sclerotic at about the distance of a third of a line from its junction with the upper and outer part of the cornea, so that the instrument, as it is thrust on, enters

¹ As much of the success of the scoop operation depends on the form of the instrument itself, I must bear testimony to the superiority of that invented by Mr. Critchett, to which he has given the name of 'æstis.' (*Ophthalmic Hospital Reports*, iv. 315, 1866.)

the anterior chamber quite at its marginal angle. Having got the point clear into the chamber, the surgeon thrusts it on for a short distance downwards and inwards, then lowers the knife into a horizontal position, and brings the point out in the sclerotic at a spot opposite to that of its entrance; the edge of the knife, which had been kept upwards, is now to be turned a little forward, and the corneal section completed. The wound now lies under the still undivided conjunctiva; this is then cut through with the knife, so as to leave a little flap of the membrane loosely covering the wound.

The next step of the operation is to remove the upper part of the iris with forceps and scissors, to such an extent as may seem desirable; then the anterior capsule is freely lacerated with the cystitome. Next the curette is to be laid upon the lower part of the cornea, and pressed in a direction upwards and backwards, so as to induce the upper edge of the lens to present at the section, and as the lens slowly advances, its egress is to be aided by the curette being steadily carried upwards, with gentle pressure, over the surface of the cornea; and if portions of the soft periphery of the cataract become detached, they are to be helped on in their upward course by repeating the gliding pressure with the curette. To prevent the epithelial surface of the cornea from being abraded during these movements of pressure, Graefe advised that the curette should be made of vulcanite instead of silver.

OPERATIONS ON OPAQUE CAPSULE.

I have elsewhere alluded to the statements of Stellwag and others respecting the so-called opacities of the capsule (p. 82). Surgically speaking, it matters not whether the capsule, which remains in the pupil after various forms of cataract operations, be in its very substance opaque, or whether it be only coated with opaque material. It obstructs vision and must be removed.

After the lens has been got rid of by solution, the anterior and posterior portions of the capsule, which have been broken through at the centre, retract and form a white ring, which is often wholly concealed when the iris is in its natural condition, only becoming visible when the pupil has been artificially dilated. Sometimes a band or two may stretch across the pupillary area.

After extraction also, it commonly happens that the shreds of torn capsule form a delicate film, blocking up the pupil; and if any slight degree of iritis has followed the operation, this film may be made additionally dense and visible by exudation of lymph. Even when the area of the pupil looks black and clear, some months after extraction, the surgeon should endeavour to keep the patient in view: for perhaps at the end of a year or so a filmy membrane will be found stretching across the pupil, so delicate as to be detected only after the closest scrutiny, and with the aid of concentrated light; and yet the existence of this film will just prevent the patient being able to read. Short of this point all objects may be seen well, and yet, for want of tact and care in detecting this slight obstruction to vision, the surgeon may lose the credit and the satisfaction of having performed a first rate operation.

In some instances, the film, which forms many months after extraction, appears to be produced by an opacity of the hyaloid membrane advancing towards the plane of the pupil after the lens and its capsule have been removed.

There are no manipulations which demand more judgment and care than those for removing capsular obstructions. The two chief points to be observed are: to make the aperture in the capsule central, so that it may correspond to the axis of vision; and to avoid isolating any portions by completely detaching them from the rest of the membrane. Loose shreds, when set floating by unskilful management, are ever afterwards a source of annoyance to the patient. Above all, the division of the capsule is to be made with the least possible disturbance of the vitreous body.

Every movement of the needle should have a definite object. It is useless to make random stabs and plunges at detached portions of capsule, in the hope of depressing them by some lucky hit; for their buoyancy will almost always cause them to return to their former position as soon as the needle is withdrawn. Delicate

bands, tightly stretched across the pupil, may be divided in the middle, and then each half will retract toward its fixed point, and leave the interval free.

When a single needle is employed to tear through a portion of capsule, it sometimes happens that the delicate membrane yields and stretches, instead of being torn, and, after each attempt, the surgeon is mortified at seeing it return to its former position. It is in such cases that it is so efficacious to use two needles at once, as suggested by Bowman.¹ There is hardly any filmy expansion, or hair-like band, that may not by this means be divided.

The lids being held apart with a spring speculum, the surgeon has both hands at liberty, and he separately introduces the needles through the cornea, until their points reach the area of the pupil. He then, according to the nature of the obstruction, either makes in the centre of the opaque membrane a small hole, and then enlarges it by drawing the points of the needle in opposite directions, or cuts, twists, or tears through some band or filament which had been holding together the margins of the pupil.

If the rules which I have said should guide the surgeon in effecting the absorption of a cataract be strictly adhered to, namely, to attack the lens at the centre, always working the needle steadily from that point towards the circumference, and to be satisfied with slow progress, without attempting to break up a large mass of lens at the earlier operations; and if he carefully avoids isolating and setting loose any portions of capsule, he will rarely find it necessary to employ any other instruments than needles for obtaining a perfectly clear pupil.

But if a case has already been unskilfully operated on, and the needle used roughly and without any settled aim, it may happen that the entire capsule containing some small remains of white lens matter has become crumpled up and rolled into an opaque mass, which is either moored in the midst of the pupil by two or three delicate bands, or is attached by a single filament, which allows the mass of capsule to float and sway to and fro with every movement of the eye. In such a case the entire mass of capsule must be extracted.

To effect this, an incision of suitable size is to be made through the cornea near its edge, and a forceps introduced, the points being kept closed until they have reached the capsule. This is then seized, and withdrawn by gentle traction, sufficient to make the retaining filaments give way.

The forceps used for this purpose must be so constructed that, when its points are separated, the iris will not fall between them. The cannula-forceps best fulfils this indication.

Far from having described in the foregoing pages all the operations which have hitherto been devised for the removal of cataract, my narrow limits, and still more a distaste for being a mere chronicler of minute differences of procedure, or abortive attempts at originality, have combined to limit my descriptions to those operations which have been approved of and practised by leading surgical authorities, or which have in some degree secured a reputation by retaining for a considerable period the confidence of the profession. A full account of all the cataract operations invented up to the present time, with a criticism of their relative value, would form a work almost as large as the present essay. I cannot, however, dismiss this most important subject of cataract without a few observations on the relative merits of the operations which are practised for its cure.

For cataract in children and young persons, solution of the lens by keratonyxis if performed with the careful precautions mentioned at p. 88, appears to me to be a nearly perfect operation. The natural curve of the cornea is preserved; the pupil remains central; in short, all the structures of the globe are left, practically speaking, in their natural conditions, except that the offending lens is gone. The treatment, it is true, extends over several months, although in infants I have seen all the lens absorbed at the end of a few weeks. But even to a young adult, what is the delay of several months, nay, in extreme cases of enforced caution in operating, what is

¹ *Medico-Chirurgical Transactions*, 1853, vol. xxxvi. p. 315.

the delay of a year, when good and lasting sight is eventually gained, compared with the patient's loss, when the surgeon, for the sake of a rapid cure, by his over-manipulation or his dangerous activity, calls up destructive inflammation in the eye he was anxious to save!

Sometimes, in the course of the most careful treatment by solution, a sudden disruption and displacement of the whole lens occurs; nothing but an immediate incision of the cornea, and removal of the irritating lens-matter, will then save the eye; but this accident seldom happens if proper precautions have been taken from the first.

With regard to extraction, all surgeons, I think, are agreed that, *provided all goes well*, the final result of a good flap operation is superior to that of any other procedure. In an eye where all the tissues are sound except the lens, such an operation, skilfully performed, with careful after-treatment until the cure is completed, is a real triumph of surgery, only to be surpassed, perhaps, by the result of an equally perfect operation by solution. But then comes the all-important question, Is all as likely to go well with the ordinary flap extraction as with some of its modifications, or with the scoop operation?

The one great source of trouble after a flap operation is prolapsus iridis. The surgeon may have done his part perfectly; his last look at the eye, before he puts on the bandage, may show him the iris in its proper position, with the pupil central, and the corneal wound in the closest apposition. For three or four days after the operation, the patient may be quite comfortable, and the eye hardly complained of; and yet when the surgeon makes his first examination, he may find the section gaping, plugged with a mass of iris, the pupil displaced, or even drawn into the wound. Speedy cure or a shapely eye are henceforth unattainable; and the operator must be content if the cornea retains its transparency, and the other tissues are not too far injured by tedious inflammation to allow of sight being ultimately restored by the formation of an artificial pupil.

I know that many surgeons, in discussing the perils incident to flap extraction, would put forward, as one of the greatest sources of danger, the largeness of the corneal wound, as involving loss of vitality in the flap or a slow process of opacity in it. But I do not think that either of these disasters is often caused by the mere length of the incision; and, on the other hand, a free opening in the cornea allows the lens to escape without bruising the edges of the wound, and, what is of still more importance, without leaving behind it any considerable fragments of its cortical portion. Now this latter circumstance is inseparable from every case in which a lens is forced to squeeze itself out through a small aperture. In doing so it must scrape off more or less of its substance, and either these fragments remain, to set up irritation in the iris, or to insinuate themselves into the wound, and interfere with its quick union; or else they are removed by too much surgical interference, too frequent introduction of a scoop, or a suction-curette, or a syringe, or by too much squeezing and pressing of the eyeball. Overmuch manipulation of the eye is, I think, the radical fault both of the modified flap extraction and of the scoop extraction, and, indeed, of most of the attempted improvements of the flap operation.

As for loss of vitreous humour, which, without the slightest fault of the surgeon, sometimes takes place as soon as the corneal flap-wound is completed, it is equally liable to occur during scoop extraction, if the scoop is allowed to pass too deeply backwards, behind the lens, so as to rupture the hyaloid membrane; and an escape is still more probable during the squeezing and pressure which are inseparable from Graefe's modified flap operation.

In giving a preference to the older flap operation, as being, *upon the whole*, preferable to the other forms of extraction, I am quite aware how much I am influenced by the fact of my having been accustomed to the constant performance of the former operation for a period of nearly twenty years before any modification of it was invented. When I tried the scoop operation in cases which appeared to be especially suitable for it, I found that, while the most successful cases left the patient with a deformed and enlarged pupil, and with the optical annoyance of circles of

dispersion, inseparable from that condition, I had in less favourable instances to contend with chronic opacity, insidiously invading the cornea, in patients whom I had selected for scoop operation in consequence of feeble reparative powers, which seemed to render dangerous the larger wound of a flap extraction.

CHAPTER XI.

GLAUCOMA.

(Plate II., fig. 3.)

'GLAUCOMA' is a term which in process of time has acquired a meaning quite different from that originally conveyed by it. Among the ancients 'glaucoma' signified opacity of the lens, and was therefore regarded by them as a wholly incurable disease, inasmuch as to remove the lens from its position would have been deemed equivalent to displacing the very seat of sight. At a later period the etymology of the word caused it to be applied to many cases of greatly impaired or lost vision attended with fixed dilatation of the pupil; for, in such cases, the change of colour which the lens naturally undergoes in old age, and some slight diminution of its transparency, combined to impart to the light reflected from the fundus of the eye a greyish or drab colour, which, in descriptions, was exaggerated into green; and much labour was expended by ophthalmic writers, not many years ago, in attempts to explain the cause of this so-called green or *glaucomous* tint. In fact, the dull greyish reflex, upon which so much stress was formerly laid, may be perceived, whenever the pupils are dilated, in the eyes of almost any old person whose lenses are beginning to be cloudy.

The word 'glaucoma' has now come to be used—without any reference to its etymology, and in a purely arbitrary sense—to signify a disease gradually involving the most important tissues of the eyeball, and, if left to itself, ending in total blindness.

It is only since the late A. v. Graefe drew special attention to the subject, that the important *premonitory symptoms* of glaucoma have been estimated at their true value. Long before his time, the more advanced stage of glaucoma, and especially the strongly marked and unmistakable outward appearances of the disease in its complete form, were perfectly familiar to the profession; but the connection between this hopeless form of blindness and an earlier stage of inflammatory action was not understood; and the merit of explaining this connection, of showing how inevitably changes, apparently of no extreme urgency, lead the way to incurable loss of sight—above all, the invention of operative means for arresting these changes, and restoring the eye to usefulness—all this merit belongs to Graefe.

I will first notice the appearances of glaucoma in its complete stage.

The patients are mostly beyond the middle period of life.

They are usually pale and unhealthy in appearance, often showing that worn expression which becomes impressed on persons who have gone through much suffering.

The eyeball, instead of having the slight degree of elasticity natural to it in health, is remarkably hard, giving to the finger almost the sensation of a stone.

The sclerotic, often marked with faint dusky patches, is traversed by large, purple, tortuous veins, which emerge abruptly, close to the margin of the cornea. Sometimes there is also a slightly-marked vascular zone.

The cornea, although it may be sufficiently transparent to allow of the iris being well seen, presents a peculiar unevenness of its epithelial surface; so that the lines of a window-frame, instead of being distinctly depicted on the corneal surface, appear wavy and irregular: and the reflected light is dull, like that from a slightly steamy

glass. In some cases the cornea is hazy throughout its substance, and occasionally the epithelium is found vesicated in small patches.

If the state of the cornea allows a good view of the iris, these two structures will usually be found in close approximation to each other, the pupil being dilated to its fullest extent; sometimes the pupil is less dilated, but irregular. The change in the appearance of the iris is very characteristic. Its sharply-defined fibrous character is lost, and it assumes a peculiar *slate-colour*. Sometimes the veins of the iris are sufficiently enlarged to be distinctly visible to the naked eye.

The lens advances very near to the cornea, and in cases of old standing is opaque. Sometimes this opacity has a milky appearance, with slight indications of striae, and the whole lens looks full and swollen, as if it had undergone maceration, and were about to burst its capsule. Occasionally the divisions between the planes of lens-fibres are very distinctly seen. The lens may vary much in colour, appearing greyish or greenish diaph, dirty yellow, or dull orange.

Perception of objects is wholly lost; sometimes even all perception of light.

An eye may present all the above-mentioned appearances in consequence of slow disease, *advancing*, with intervals of quiescence, during months or even years; or, on the other hand, the same appearances may be the result of an acute inflammatory attack, *coming on* in the most sudden manner, and within a few days producing all the changes above noticed, with the exception of the opacity of the lens, which takes place more slowly.

Mere inspection of an eye in which glaucoma is complete will not enable the surgeon to decide whether the morbid changes have been the result of the *chronic* or the *acute* form of the disease.

I have already alluded to the merit of Graefe, in having been the first to connect *that well-known* incurable condition of the eye, to which alone the term glaucoma was formerly applied, with a definite train of premonitory symptoms, marking a period during which surgical treatment might be of service. These peculiar premonitory symptoms consist in intermittent attacks of dimness of sight. A patient perhaps sees well up to the middle of the day, then objects appear as if involved in smoke, and reading becomes difficult or impossible. This dimness may last for the rest of the day, and the next morning it may have quite passed off, to return again in the course of a few hours. This intermittent dimness may go on for months, with little, if any, external appearance of inflammation; in other cases, the onset of dimness is attended with slight redness and watering of the eyes. In fact, unless the peculiar premonitory symptoms of incipient glaucoma are well understood, a case of the most serious kind may be lightly regarded as one of unimportant catarrhal ophthalmia.

A luminous object, as a candle or a lamp, appears surrounded with a halo of prismatic colours. The iris approaches the cornea, and the pupil is inactive, although perhaps not dilated; and, unless the attack be very slight, the surface of the cornea, instead of presenting a brilliant mirror-like smoothness, will appear slightly dull, like a glass that has been breathed upon; so that the lines of the window-frames will be reflected in a faint and wavy form. This uneven and *dull* appearance of the corneal epithelium is a very valuable diagnostic mark in all stages of glaucomatous disease, and will often arouse the suspicions of a careful observer in cases which might otherwise be thought unimportant. It is invariably present in all advanced and confirmed cases of glaucoma. The premonitory obscurations may persist for weeks, with occasional interruptions, even for months; and patients may be liable to intermittent attacks for a year or more, before any outburst of acute inflammation occurs. Neuralgia in the ophthalmic division of the fifth nerve is commonly added to the other premonitory symptoms.

If the eyeball be carefully examined during any period of glaucomatous disease, it will be found in some degree harder than natural. This hardness goes on increasing, until, in the last stage of glaucoma, the globe feels almost like a ball of stone.

I know of no instance in which the *tactus eruditus* of the surgeon is more

severely tested than in examining some of these incipient cases of glaucoma. The same eyeball may suggest to two able examiners different degrees of hardness, or they may even disagree as to whether the eye be abnormally hard at all.

While the patient gently closes the lids, the surgeon is carefully to apply the tips of his fingers upon the upper part of the globe, lightly pressing upon its coats. And again, when the patient opens the lids and looks upwards, the surgeon presses the middle part of the lower tarsus steadily against the sclerotic, just below the cornea, and carefully notes the degree of resistance he meets with. I need hardly say that too great softness of the globe is as much a mark of disease as too great hardness, and that, to discriminate truly between the various degrees of what is too hard and what is too soft, the surgeon must familiarise himself with the exact amount of firmness and elasticity indicative of a sound state of the coats and humours of the globe, by means of that careful fingering with repeated practice alone can give.

Donders, Bowman, and others have devised formulæ for noting down the amount of tension existing in the globe, but the gradations are so manifold, that it is barely possible to tabulate them correctly according to any fixed plan.

Rest of the eyes, careful attention to general health, and iodide of potassium internally, I have found to constitute the best mode of treatment in this stage; but the patient must be warned as to the true significance of the symptoms, and as to the probable onset eventually of acute glaucoma.

It was to the ophthalmoscopic appearance of the optic nerve and its vessels, in all stages of glaucomatous disease, that Graefe drew such special attention. In well-marked cases the optic nerve appears concave, and the retinal vessels, instead of passing off from their point of emergence in a straight direction, to ramify on the retina, begin by curving over the edge of the cup-like depression at the end of the nerve.¹ Very slight pressure on the globe with the finger causes visible pulsation in the retinal vessels; or this pulsation may exist without external pressure.

In the slowly-advancing early stage of glaucomatous disease, the depression of the optic nerve may be so trifling as to escape observation; but in confirmed cases it is very marked. When the disease has come to a crisis, and acute glaucoma has set in, the details of the optic nerve and retina cannot be seen with the ophthalmoscope, owing, I believe, in great part to the condition of the corneal surface, which produces irregular refraction of the rays of light. In the advanced stage of glaucoma a dull red glow is sometimes all that can be seen.

As disease goes on, the dimness of sight, instead of being intermittent, becomes permanent, and the field of vision gradually contracts, so that at last the patient in viewing objects seems to be looking at them through a small hole in a screen. Sometimes, however, this narrowing of the field of vision does not take place, the dimness being pretty uniformly diffused. By this time other marked changes have taken place in the globe. It has acquired a peculiar stony hardness; the veins on the sclerotic emerge abruptly near the edge of the cornea as thick purple trunks: the pupil gradually dilates until in old cases the iris almost disappears, acquiring at the same time a peculiar slaty tint. Eventually the veins of the iris enlarge, and are especially noticeable as a ring-like plexus near the pupillary margin. The lens at last becomes opaque, milky-looking, and indistinctly striated; it is often of a greyish drab, dirty yellow, or dull orange, and marked with earthy streaks and patches. Its threefold division is often very well marked, as if by undergoing maceration in water, it had swollen up and were about to burst its capsule. By this time even perception of light is usually quite lost.

From what I have already stated as to the various changes in glaucoma, it will be understood that it is by a careful comparison and estimate of several morbid appearances taken together, that the disease is to be discriminated, and not by the presence of any one distinctive sign. If mere abnormal hardness of the globe be

¹ Plate II. fig. 8. This is a diagram, not a drawing from an individual case. It shows, in a rough way, the abrupt curve of the vessels, the concave form of the optic disc, and the grey tint which the latter sometimes assumes in the very advanced stage of true glaucoma, or of grey atrophy of the optic nerve.

assumed as the proof of glaucomatous change, several forms of inflammation and degeneration quite distinct from glaucoma may be mistaken for that disease. A 'cupped' condition of the optic nerve may simply be the result of chronic wasting. Coloured halos around luminous objects are commonly associated with ordinary catarrhal ophthalmia. But let all these symptoms co-exist;—intermittent obscuration of vision, prismatic halos, fixity of the pupil, increased hardness of the globe, a changed condition of corneal epithelium, cupping of the optic nerve—and the diagnosis becomes an absolute certainty.

I have said that the course of the glaucomatous process is usually more or less gradual, a longer or shorter premonitory stage preceding the onset of an acute attack; but this sometimes comes on suddenly, frequently in the night, the patient having gone to bed apparently well, and being aroused from sleep by intense neuralgic pain to find himself all but blind. When such an attack occurs, on account of the hazy condition of the corneal epithelium, or some change in the vitreous body, from both causes combined, the optic nerve and retina cannot be discerned, and the ophthalmoscope only reveals a dull red glow from the fundus.

Treatment of glaucoma.—While cases of chronic glaucoma which had advanced to their last stage were abandoned as wholly incurable, and beyond all treatment; those of the acute form (under the name of *ophthalmitis interna*, *ophthalmitis arthritica*, &c.) were formerly treated on antiphlogistic principles, pushed to the severest extremes; profuse bleeding, both local and general, and mercury in salivating doses, being the common means employed to check the progress of disease. Some practitioners regarded gout as the primary cause, and, in addition to depletion, employed colchicum, or other anti-arthritis.

In spite of every form of treatment, glaucoma remained the *opprobrium* of ophthalmic medicine; and the announcement, therefore, of its curability by means of an operation at once attracted general attention. In 1857 Graefe¹ published an account of this operation of 'Iridectomy,' and he also brought the subject before the Ophthalmological Congress which met at Brussels in that year. An incision was to be made through the cornea, close to the sclerotic; a considerable portion of the iris was then to be grasped with a forceps, drawn out, and cut off. By this operation the 'intraocular pressure,' which was the cause of all the phenomena of glaucoma, would at once be removed.

His operation is performed as follows. The globe having been fixed with a forceps, a lance-knife is passed obliquely through the sclerotic, about a line and a half from the spot where it blends with the cornea, so as to make a wound penetrating into the anterior chamber. An iris-forceps is then passed through the wound, a fold of iris seized, drawn out, and then cut off close to its ciliary attachment. Graefe and others lay particular stress upon the iris being removed quite up to this point, but I do not believe it to be at all essential. I have always performed the operation with a Beer's knife, making, in fact, a corneal wound like the upper section for flap extraction, but on a much smaller scale. The wound is a good deal anterior to that recommended by Graefe, and passes through the true cornea, but close to its sclerotic union. The iris, consequently, is not divided quite up to its ciliary attachment; and yet I have found the result of the operation just as satisfactory as that first described. In acute glaucoma the lens always advances forwards, close up to the cornea, and is therefore endangered by the thrust made with the lance-knife; whereas, in using Beer's knife, in the way I have mentioned, its point is always kept in front of the iris as it lies against the projecting lens. The long knife devised by v. Graefe for peripheral linear extraction will be found even more convenient than a Beer's knife. It appears to me that, if a peripheral portion of iris

¹ See his essay in the *Archiv für Ophthalmologie* (vol. iii. p. 450), entitled *On Iridectomy in Glaucoma, and on the Glaucomatous Process*. Also (vol. iv. p. 127, 1858), *Farther Clinical Remarks on Glaucoma, Glaucomatous Diseases, and the Curative Effects of Iridectomy*. These two essays, together with another *On Coremorphism as a Remedy in Iris and Iridochorioiditis*, were translated, under slightly changed titles, by Mr. J. Windsor, and published by the New Sydenham Society (vol. v. 1859).

is removed, sufficient to establish a free communication between the anterior and posterior chambers of the aqueous humour, the object of the operation has been attained.¹

Hancock recommended the following operation in glaucoma, as being greatly preferable to iridectomy. The point of a cataract-knife is inserted at the lower and outer part of the edge of the cornea, and carried in a direction obliquely downwards, dividing the sclerotic to about the extent of two lines, and penetrating through the corpus ciliare into the vitreous humour. The incision also divides the attachment of the iris, and the delicate fibres constituting the 'ciliary muscle.' The division of these fibres, which I have already spoken of as chiefly constituting the apparatus for changing the form of the lens in the act of accommodation, was regarded by Hancock as the essential point of the operation, since he believed their spasmodic contraction to be the primary cause of the phenomena of glaucoma.

In performing the operation of iridectomy, great care must be taken to avoid wounding the lens, which, as I have said, always projects towards the cornea, and is sometimes in actual contact with it. This danger is avoided by making the corneal incision in the way I have recommended.

A good deal of blood usually flows from the cut iris into the anterior chamber, sometimes quite filling it. This blood soon becomes absorbed, if the eye is kept at rest, and bandaged with a carefully adjusted amount of pressure, for twenty-four hours. When, after this period, the eye is examined, the cornea is found to be clear, and the peculiar unevenness of its epithelial surface has given place to the normal mirror-like smoothness.

The recovery of sight after a well-timed and well-performed iridectomy is most remarkable, in many cases almost amounting to the restoration of former good vision, where it has been done before much organic change has occurred in the optic nerve, and where the loss of vision mainly depended directly on the excessive pressure and in a minor degree on atrophic degeneration. It is for this reason that iridectomy gives better results in this form of glaucoma associated with inflammation (*glaucoma cum ophthalmia*) than in the more chronic form.

Recently sclerotomy has been advocated by some as a substitute for iridectomy, which even sometimes succeeds where iridectomy has failed permanently to relieve excessive pressure. With a long narrow Graefe's extraction knife an incision is made in the sclero-corneal junction tangential to the circumference of the cornea. After the periphery of the anterior-chamber has been transversely divided by the point of the knife, and a counter-puncture made, some leave a small bridge of sclero-corneal tissue undivided; others cut out through this, but leave the conjunctiva unsevered. The tendency to prolapsus iridis may be diminished by the previous use of eserine. But this drug is not only of use as a preliminary to iridectomy; it is of the highest value in lowering excessive intra-ocular pressure. A solution of the sulphate of eserine (gr. ii. to ʒj aq. dest.) dropped at short intervals several times into the eye will not unfrequently produce a decided remission of tension in cases of acute *glaucoma cum ophthalmia*, and enable the surgeon to perform iridectomy or sclerotomy with much less risk of intra-ocular hæmorrhages. It is scarcely less useful in the chronic forms of the disease.

The precise rationale of iridectomy as a curative means still remains to be accounted for; and it must so remain until we become acquainted with the first origin of glaucoma. We speak, indeed, of the disease as consisting in 'intra-ocular pressure,' but why the fluid contents of the globe are in excess, so as to cause this pressure, is unexplained. We must be satisfied practically to employ iridectomy or sclerotomy, without being able to give any clear theoretical reason for our procedure.

¹ If this view be correct, the explanation which those who prefer Hancock's operation have offered, as accounting for the beneficial effect of iridectomy, becomes inconclusive. They consider that the unintentional division of the fibres of the ciliary muscle, during the performance of Graefe's operation, and not the removal of the piece of iris, constitutes its real value. But if iridectomy, performed in the way I have recommended, be found as effectual as when the iris is removed quite up to its ciliary attachment, it follows that division of the ciliary muscle can in no way contribute to the beneficial result of the operation.

CHAPTER XII.

DISEASES OF THE LACRYMAL APPARATUS.

THE lacrymal apparatus comprises the lacrymal gland, which secretes the tears—the puncta and canaliculi, which convey them into the lacrymal sac, where they temporarily accumulate—and the lacrymo-nasal canal, whereby they are finally conveyed into the lower chamber of the nose.

If we consider the small calibre of the canaliculi, we can readily understand that a very slight degree of thickening in the delicate membrane which lines them, or a trifling displacement of the puncta, can suffice to disarrange the mechanism of taking up and carrying on the tears; and accordingly we find that watering of the eye (*epiphora*) is a frequent symptom in various forms of conjunctival inflammation. It also constitutes of itself a troublesome condition, which is constantly being brought under the surgeon's notice.

If the puncta are quite impervious, of course the tears must trickle down the cheek as fast as they are secreted. A contraction or stricture of the puncta or canaliculi will cause a less complete overflow. If the lacrymo-nasal canal be strictured, or its outlet obstructed, the tears passing into the sac will accumulate there, and, together with the pent-up mucus, form a swelling termed *mucocoele*. Unless relief is obtained, the distended sac becomes inflamed, and pus is formed, which eventually discharges itself through an opening in the skin, constituting true *fistula lacrymalis*. This term, however, is often incorrectly applied to abscess of the sac without any perforation of the skin.

When a case comes before us in which there is a continual watery state of the eye, our attention should be at once directed to the puncta. These apertures, in a healthy state, are in contact with the ocular conjunctiva, so that, to bring them into view, it is necessary to draw the margin of the tarsus a little away from the eyeball. If the conjunctiva lining the lower lid has become considerably thickened from chronic inflammation, the edge of the tarsus may be so much everted as to cause the punctum to face upwards, or even directly forwards. In such a position it can no longer take up the tears, which accordingly run over the edge of the lid. In extreme cases of *lippitudo* and chronic ophthalmia, the puncta, still retaining their natural position, are sometimes found to be so completely obliterated that their position can no longer be detected.

If the puncta are in their natural position, and their openings appear unobstructed, and yet no tears can be made to regurgitate through them when the point of the finger is firmly pressed against the lacrymal sac, just below the tendon of the orbicularis palpebrarum, we may suspect some stricture to exist in the canaliculi. We can ascertain this only by exploring them with a fine probe. This may seem to be a very simple matter; but it requires considerable care and tact, without which much serious mischief may result. The membrane lining the canals is extremely delicate, and any want of gentleness in passing the probe may tear the membrane, and so give rise to fresh obstruction. We must bear in mind the abrupt turn which the canal makes at a short distance from the punctum. In passing a probe into the lower canaliculus, the instrument should be directed almost vertically downwards for about half a line, and then turned inwards towards the nose, in which direction it will pass on, should no stricture exist, until its point strikes against the inner wall of the sac, where it lies against the bone. During the whole process of introducing the probe, the tarsi should be kept on the stretch, by drawing outwards the external canthus.

Except to a practised hand, it is often difficult to detect whether the point of the probe is arrested close to the junction of the canaliculus with the external wall of the sac, or whether the point has reached the internal wall. In the former case any onward pressure with the instrument produces a slight dragging of the tarsus;

whereas contact of the probe with the inner wall of the sac not only conveys to the hand a peculiar feeling of firm resistance, but at once causes all movement of the tarsus to cease.

If the canaliculi be found free from stricture, and the sac forms a distinct prominence below the inner canthus, it is pretty certain there is an obstruction at the lacrymo-nasal canal. If this canal be perfectly closed, while the canaliculi are free, firm pressure of the finger on the swollen sac will cause its contents to escape at the puncta; but if the canal, although narrowed, be pervious, steady pressure in a direction downwards and a little backwards may overcome the resistance of the stricture; the swelling then suddenly yields, and the contents of the sac pass into the nose.

When we consider that the membrane lining the outlet of the lacrymo-nasal canal is that common to the chambers of the nose, we cannot be surprised that catarrhal inflammation of this membrane should be a frequent cause of lacrymal obstruction. If pressure on the sac suffices to empty its contents into the nostril, the inconvenience of the partial obstruction at the outlet may be kept in check by the patient taking care frequently to make this pressure, and to use at the same time other means for restoring the lining membrane of the sac as well as that of the nose to a more healthy condition. But if this pressure is omitted, and the tears and mucus are allowed to collect and to distend the sac, this distension, under some attack of catarrhal inflammation, may suddenly transform the chronic disease into an acute one. Pain is then felt in the part; the lids become red and puffy,—sometimes assuming an erysipelatous appearance; and the patient is quite unable to separate the tarsi. The swollen sac feels hard to the touch, and even slight pressure on it is extremely painful, while it fails to press out anything from the puncta.

These symptoms show that suppuration is taking place within the sac. If the case is left to itself, the pus escapes by bursting through the skin, and the opening frequently remains fistulous, allowing the tears, which have passed through the puncta into the sac, to trickle out upon the cheek, thus constituting a true *fistula lacrymalis*. After all inflammation has passed away, and the redness and swelling which attended the formation of the abscess have disappeared, the fistula often contracts to such a small aperture, that, were it not for the tears which slowly distil from it, the opening would hardly be perceptible. It is about the size of a pin-hole, and almost resembles one of the puncta in minuteness of aperture.

Treatment of lacrymal obstructions.—These obstructions, varying as they do from a slight thickening of some portion of the lining membrane of the sac or nasal canal, causing occasional watering of the eye, up to a total occlusion of the nasal canal, with displacement or stricture of the puncta and canaliculi, cannot of course all require the same kind of treatment. Astringent solutions of alum or tannin may be dropped into the corner of the eye, so that they may follow the course of the tears, and thus reach the thickened membrane. This object may be facilitated by slitting up the caniculus in the manner hereafter to be described. Each time the drops are used, the sac should be previously emptied, by pressing the point of the finger upon it in a downward direction. Should the lining membrane of the nose be in a thickened state, injections of astringent lotions into the nostril are of service; and in all cases attention to the general health and suitable tonic medicines are indicated.

Warm water-dressing should be applied whenever acute inflammation of the sac sets in with the symptoms I have described. This form of applying warmth and moisture is, in all affections of the lids and parts about the eye, to be preferred to poultices, as the latter frequently produce a troublesome form of eczematous eruption. Diligent application of water-dressing for four-and-twenty hours will frequently subdue acute inflammation of the sac to such an extent that not only do the redness and swelling of the lids disappear, but the thickening of the internal membrane gives way; so that gentle pressure over the sac suffices to empty its contents into the nose, and the case returns to its chronic condition. Should this not be the case, an incision must be made into the sac, and exit given to the pus.

There is hardly any form of local disease which has given rise to a greater variety of surgical treatment than chronic distension of the lacrymal sac, and stricture of its nasal duct. The distended sac has been compressed by an apparatus of pads, adjusted by means of springs and screws. The strictured sac or duct has been subjected to gradual dilatation by means of strings of catgut, introduced through an opening made into the sac, and brought out into the nostril; strings of increasing thickness being used as the canal would admit of their passage. Dilatation of the stricture was at one time attempted from below, by means of curved sounds, introduced into the sac from the nostril; but these instruments were difficult to introduce, there was great risk of breaking with them some of the fragile bones in the neighbourhood of the nasal duct, and they could not reach a stricture situated high up towards the entrance of the canaliculi. At one time metal tubes were placed in the cavity of the sac, which were intended to be healed in, and permanently to occupy its cavity; but Nature, disliking foreign bodies, even when introduced by a surgeon, always rebelled against them, and did her best to dislodge them, either upwards or downwards. The style maintained its ground longest, and formed the *ultima ratio* in every case of obstinate lacrymal obstruction. It was made long enough to reach from just below the tendon of the orbicularis palpebrarum, where an incision was made into the cavity of the sac to admit it, to near the floor of the nostril. The upper end was furnished with a nail-like head, to support the style in its proper position; and it was intended that the tears, entering by the puncta and canaliculi, should come into contact with the piece of metal, and glide down by the side of it into the nose. The style was to be taken out every day, cleansed and replaced; and at first the cure appeared perfect; but patients, from timidity, awkwardness, or carelessness, neglected this precaution, the instrument was seldom, in some cases never, removed, and eventually it became encrusted with earthy deposit from the tears, or was consumed by oxydation; the skin around the nail-shaped head was drawn in, and at the same time blackened with the sulphuret of silver,—in short, the style, so highly praised at first, became at last a source of annoyance and disappointment.

Bowman¹ suggested a very simple and useful operation, which, in many instances, suffices to cure *epiphora* resulting from contraction or displacement of the puncta, while at the same time it affords a ready access to any obstruction that may exist in the course of the sac or lacrymo-nasal canal.

Suppose that, in consequence of chronic ophthalmia, or from any other cause, the lower punctum has become displaced, so that, instead of facing towards the eyeball, it is directed upwards and forwards; the tears in such a case will run over the edge of the lid; and the object of the surgeon must be to transfer, as it were, the displaced punctum to a position where it can catch the tears before they overflow the border of the tarsus. The lid being put upon the stretch, a fine grooved director, or, in default of that, an ordinary punctum-probe, is to be passed along the whole course of the canaliculus, and held firmly there, while a fine sharp-pointed knife is run along the probe, as far as the caruncle, so as completely to lay open the canal, and thus extend its orifice backwards to the point where the tears accumulate. A very handy little knife, with a slightly bulbous point, has been invented, with which the canaliculus can be slit up without the use of any probe or director.

For several days after the incision has been made through the upper wall of the canaliculus a probe must be passed along its track, to prevent the lips of the wound growing together. In some persons it may be necessary to use the probe for ten days or more; in other cases there is hardly any disposition in the edges of the wound to unite.

When the overflow of tears depends simply on faulty position of the punctum, this laying open of the canaliculus may of itself effect a cure. In cases of obstruction in the lacrymal sac or its nasal duct, the incision affords an easy access to the seat of stricture.

Occasionally, however, another complication exists in a narrowing of the canali-

¹ *Medico-Chirurgical Transactions* for 1851, p. 338.

culus just at its point of communication with the sac, which may prevent the passage of a probe sufficiently large to act upon the stricture. In such a case a small straight cannula, containing a lancet-shaped point, which may be protruded or withdrawn by means of a spring,—in fact, Stafford's instrument for dividing urethral stricture, made on a miniature scale,—must be carried along the canaliculus, and employed upon the constricted spot.

The probes for dilating strictures in the sac or its canal must be of various degrees of thickness, but all sufficiently strong to sustain the requisite amount of pressure without bending. They are best introduced by the surgeon standing behind the patient; and it will be found advisable to avoid using those of too small a size, as they are of course more likely than those of a larger size to catch in a fold of membrane, or even to pierce the membrane covering the bony walls of the canal.

The tarsus being put on the stretch, the probe is passed along the newly-opened canaliculus until its extremity strikes against the inner wall of the sac. Still keeping its extremity in contact with this part, the probe is raised to a vertical position, and then carefully carried downwards to the seat of stricture. The canal inclines somewhat backwards, and this inclination is to be carefully borne in mind. The surgeon must feel his way with the point of the instrument, and be on his guard against using unnecessary force. In cases of old dilatation of the sac, its relaxed lining membrane readily catches in a fold against the point of the probe, and the surgeon must learn to discriminate between a check arising from this cause, and the obstacle encountered by the instrument becoming impacted in the constricted lacrymo-nasal canal. The length of the instrument which has been passed in, and the patient's own feelings, will prove whether the point of the probe has entered the nasal cavity.

It sometimes happens that, immediately after the first passage of the probe, the surgeon is able, by pressure over the sac, to force all its contents down into the nose; but if there has been much difficulty in passing the instrument, the membrane becomes swollen, and will allow the contents of the sac to pass only after the swelling has been relieved by fomentation.

No fixed rules can be laid down as to the frequency with which the probe is to be used, nor as to the length of time required for a cure. This will vary from a few weeks to several months, and relapses frequently occur long after the stricture appears to have been completely overcome. Too frequent use of the probe will set up irritation, and induce a more abundant muco-purulent secretion. When this takes place, the probe must be laid aside for a week or two, and fomentation, with water-dressing at night, be substituted.

During the whole course of treatment by means of the probes, the patient must never neglect several times a day to press out the contents of the sac, endeavouring to do this in a downward direction; or, if this cannot be effected, by pressure through the puncta.

Those who are about to treat a case of long-standing lacrymal obstruction by the passage of probes, should clearly understand how much care, tact, and patience such an undertaking requires. In consequence of the minuteness and delicacy of the parts concerned, the treatment of a stricture in the lacrymo-nasal duct demands even greater care and skill than that of a stricture in the urethra; and I am sure that those who have seen much practice will bear me out in asserting, that by far the greater part of obstinate and dangerous cases of the latter kind are due to meddling surgery rather than to any original disease.

The surgeon must bear in mind that the walls of the lacrymal sac and duct are composed of extremely brittle and fragile bones, and the rough introduction of a probe may either break some of these, or tear away the delicate and vascular membrane which covers them. Besides, as the lacrymo-nasal canal is a bony tube, all thickening of its lining membrane must take place concentrically; and therefore any undue violence, by setting up inflammation, is sure to increase instead of lessening the cause of stricture. On these grounds the practice lately advocated of forcibly

pushing through the obstacle probes of very large size, and of cutting it in several directions with a strong, narrow-bladed knife, should not be hastily adopted.

Even when all possible care and skill have been employed, the treatment of stricture in the lacrymal passages, by the means just described, is often extremely tedious; for the affection may be complicated with great dilatation of the sac, caries of the adjacent bones, or false passages of various kinds, resulting from previous mismanagement.

Dacryolithes.—This term has been applied to certain concretions which are sometimes met with in the lacrymal passages, in the canaliculi, in the sac, or in the ducts of the lacrymal gland, caused by the earthy salts contained in the tears becoming deposited in the form of a calculus. Watering of the eye, repeated attacks of inflammation in the sac, or swelling and suppuration about the canaliculus, and pain when the part is pressed upon, are the more obvious symptoms. A probe carefully passed into the canaliculus, or through it into the sac, would detect the presence of the concretion, which must be cut upon, and extracted with a scoop or other instrument.

Irritation of the lacrymal passages is sometimes caused by the intrusion of a detached eyelash into one of the canaliculi. In this curious accident the hair enters at the punctum, and passes on as far as the abrupt bend which the canal makes at about a line's distance from the orifice. Here it is arrested; its point protruding to a greater or less extent, and irritating the caruncle and semilunar fold. The symptoms induced are a pricking and itching about the inner canthus, with reddening of the neighbouring conjunctiva. If the hair be short, its point will protrude so little as to make it very difficult of detection; on its withdrawal, all irritation at once ceases.

DISEASES OF THE LACRYMAL GLAND AND ITS DUCTS.

The works of foreign writers present a formidable array of diseases affecting this gland, almost every form of acute and chronic inflammation, and enlargements, both simple and malignant, being recorded; while our own countrymen appear to have met with but few cases of the kind. My own experience would lead me to believe that, compared with the other glandular structures of the body, the lacrymal gland is very rarely the seat of disease. Its sheltered position beneath the projection of the frontal bone guards it, to a great extent, from external violence, and it appears but seldom to participate in the inflammation of neighbouring tissues.

One rare affection consists in an accumulation of tears in one or more of the obstructed excretory ducts, whereby a cyst-like tumour is formed in the upper lid (*dacryops*), becoming very visible when the lid is everted. If one of these enlargements is punctured, without attention being paid to the after-treatment of the case, the opening is apt to become fistulous (*dacryops fistulosus*), the lacrymal secretion continuing to distil through a minute aperture in the skin. Such a case may be treated on the same principle as a fistula of the parotid gland, namely, by passing in at the opening a thread, which, having been carried through the thickness of the lid, and brought out at its conjunctival surface, has a small knot made at one end. This knot is then drawn into the fistula, and, by continued traction of the other end, is made to ulcerate its way through the conjunctival surface. The tears being thus diverted, the fistulous orifice in the skin may be closed by paring and aniting its edges.¹

Should the lacrymal gland really become the seat of malignant deposit, or should it be deemed advisable to extirpate it on account of chronic enlargement, or for any other cause, the operation would be a simple one, and would offer nothing worthy of remark.

In the only instances, three in number, where I have myself extirpated the

¹ See a well-reported case of *dacryops*, by Hulke, *Ophthalmic Hospital Reports*, vol. i. p. 287, 1850. In this instance a loop of thread was made to include a certain portion of the conjunctiva.

gland, it was not the seat of disease, but was removed to do away with the inconvenience of the overflow of tears, the puncta and canaliculi having been wholly destroyed by extensive burns. In one of these cases an artificial pupil I had made would have been rendered almost useless, in consequence of the flooding of the eye with tears, had their secretion been allowed to continue.¹

CHAPTER XIII.

DISEASES OF THE EYELIDS.

So many various tissues enter into the formation of the eyelids that they must necessarily be liable to a great variety of diseases; but it would be absurd to attempt a description of all the morbid conditions which they share with the other portions of the common integument of the body.

The *orbicularis palpebrarum* is subject to a spasmodic twitching of some of its fibres, usually those of the lower lid, producing a visible quivering of the skin, popularly termed the 'live-blood.' To persons of an irritable nervous system this becomes teasing from its frequent recurrence. It is occasionally the result of intestinal irritation, especially that produced by ascarides, when a few doses of purgative medicine, followed up by tonics, usually suffice to put an end to the annoyance.

Epicanthus is a term applied to a slight deformity, sometimes observed in children, consisting in a crescentic fold of redundant skin at the inner corner of each eye, partly or wholly concealing the caruncle. It is associated with a depressed form of the nasal bones, and if, in after life, the bridge of the nose becomes more prominent, the fold of skin, to a certain extent, diminishes, although it never wholly disappears. *Epicanthus* imparts to the face an unpleasant, Chinese expression; and the only cure is by pinching up and removing a vertical fold of skin on the median plane, just between the eyebrows, and then bringing the wound accurately together.

Ptoxis, or drooping of the upper lid, may exist in various degrees, producing merely a slight deformity, or becoming complete, so as wholly to obstruct vision. It will be spoken of under 'paralysis of the third nerve.' In some cases of congenital drooping of the lids, it is possible that the levator palpebræ muscle may be altogether wanting. Patients with this defect have no power of moving the lids except by calling into action the occipito frontalis muscle. The lids do not present that transverse fold in the skin, which, in the normal state, corresponds to the upper part of the eyeball, but are smooth and unwrinkled from the eyebrow to the tarsus, while the forehead is furrowed by the frequent action of the occipito frontalis.

The terms *Eutropion* and *Ectropion* are respectively applied to the inversion and eversion of the margins of the lids.

The simplest form of *eutropion* is that which is occasionally met with in children, the subjects of irritable ophthalmia, as a result of spasm of the *orbicularis palpebrarum*. Extreme intolerance of light induces this muscle to contract so often and so forcibly that at last the lower tarsus rolls over against the globe, causing an inversion of the eyelashes, which greatly adds to the patient's distress. Contractile collodion, painted on the skin of the lower lid, draws the part into a proper position, and keeps it so while suitable remedies are being employed to subdue the original disease.

A similar spasmodic inversion of the lower lid happens to old persons, in whom the skin is relaxed and the tarsus flaccid. The muscular contraction is repeated until at last the lid becomes so rolled upon itself, that both the cilia and the tarsus are completely hidden, and the border of the lid appears to be formed of common

¹ See *Guide to the Practical Study of Diseases of the Eye*, 2nd edition, 1859, p. 417.

integument. In these cases of extreme inversion the irritation is really much less than when the inversion exists to a slight degree. For in the latter case the points of the cilia are brought into direct contact with the ocular conjunctiva, while in the former case the tarsus rolls over so completely, that the points of the cilia become buried in the fold of palpebral conjunctiva, and consequently do not come into contact with the globe at all.

A far more severe and obstinate kind of entropion is that which follows chronic inflammation of the palpebral conjunctiva, especially neglected or maltreated purulent ophthalmia. The upper tarsal cartilage becomes so much curved upon itself, that the whole range of eyelashes turns backwards against the globe. This curving of the tarsus is often aggravated by the long-continued application of solid nitrate of silver and sulphate of copper to a granular conjunctiva. If in such cases we evert the lid, we find a pale smooth cicatrix occupying its deep concavity. Partial or complete inversion of the margin of the lids may also result from contraction of the conjunctiva, following injury from acids, caustic alkalies, or burns.

A great variety of operations has been devised for the cure of entropion. In that form, so common in old persons, where the inversion is owing to contraction of the orbicularis muscle acting upon a flaccid lid, a cure can usually be effected by removing an elliptical portion of the skin of the lid, together with the subjacent fasciculus of muscle, and then accurately uniting the wound with fine sutures. It requires care exactly to calculate what quantity of skin should be taken away; and of course the removal of too large a portion would cause eversion of the lid, and so produce a deformity of the opposite kind.

If the tarsal cartilage be so much curved that removal of skin is insufficient to draw the eyelashes away from the globe, recourse may be had to an expedient suggested by Streatfeild. The skin of the lid being carefully dissected up, sufficiently to expose the convex surface of the tarsal cartilage, a long narrow wedge-shaped slice is cut out from this, so as to form a groove extending the whole length of the tarsus. The curved cartilage thus becomes bent backwards, as it were, and the skin being restored to its position, is united along the cut edges with a few fine sutures.

Should all these plans fail, and the eyelashes still irritate the globe, the whole row must be dissected off, together with that portion of the tarsal margin in which their roots are imbedded.

Ectropion, or eversion of the lids, may exist in the most various degrees. Its worst form is seen as a result of burns of the face, followed by extensive contraction of the cicatrices.

A spasmodic form of ectropion is often seen in purulent ophthalmia of infants, and in scrofulous and irritable ophthalmia of older children. In infants the unsightly appearance of the bright red and swollen conjunctiva gives rise to great alarm in those who have the care of the child; but they may be assured that, as the inflammation subsides, the deformity will gradually cease.

The chronic forms of *ectropion* in adults, which are produced by granular thickening of the conjunctiva after purulent ophthalmia, or by the contraction of cicatrices in the skin surrounding the palpebral aperture, the result of ulcers, burns, exfoliation of bone, &c., require a variety of operations, according to the special nature of the case.

When, after chronic ophthalmia, the everted conjunctiva of the lower lid presents a thick mass of granular excrescences, without any material elongation of the tarsus, or disease of the neighbouring skin, a cure may sometimes be effected by removing with scissors the greater portion of the palpebral conjunctiva, and then uniting the edges of the wound with very fine sutures. These may be left to ulcerate out by themselves, the lid being kept in proper position by the aid of a pad of lint laid along the margin of the tarsus, and fixed by means of several layers of lint saturated with collodion. In this way the lids are kept in contact with each other, and the apparatus need not be disturbed for several days. When the wound in the palpebral conjunctiva is closed, the loose stitches may be removed, and the pad of lint replaced until the cure is complete.

In very old and severe cases of ectropion, the tarsus becomes so much stretched, that, in addition to the removal of conjunctiva, it is necessary to take away a wedge-shaped portion of the elongated lid itself. Still worse cases, such as those resulting from burns or disease of bone, may require the formation of a new eyelid by the transplantation of a portion of adjacent healthy skin.

Trichiasis consists in an irregular growth of the eyelashes, the general form of the tarsus itself not being changed. *Tinea ciliaris* very commonly causes trichiasis, by inducing cicatrisation about the roots of the cilia. Sometimes three or four fine eyelashes present their points towards the globe, or even a single hair will grow in this direction, all the other hairs maintaining their natural position.

Trichiasis, when existing only to a slight extent, causes constant annoyance to the patient, by a sense of pricking, and by the constantly irritable and watery state of the eye which it induces. If only a few hairs grow irregularly, the removal of the entire tarsal margin need not be resorted to. The offending hairs must be carefully plucked out from time to time; or if they form a little group, they may be removed by dissecting out the small portion of lid external to the tarsus itself, in which their roots are implanted, and then uniting the wound with a suture.

To draw out an eyelash by the root seems a very simple and trifling matter; and yet there are few surgical manipulations in which care and the skilful use of a well-made instrument are so necessary. The cilia forceps one commonly meets with are liable to cut the hair instead of merely grasping it firmly; and the stiff broken stump of a hair causes far more distress to the patient than its natural fine point. The hair should never be sharply jerked out, but removed with a slow steady pull.

INFLAMMATION OF THE LIDS.

The eyelids are of course liable to the various forms of inflammation which attack similar tissues in other parts of the body. A few inflammatory affections of the lids seem to demand notice on account of their presenting peculiarities of appearance, or being distinguished by special names.

A *stye* (*hordeolum*) is in fact a minute boil. It begins at the very edge of the lid, as a small, red, tense swelling, and at first is merely troublesome by the itching and sense of stiffness it occasions. As the inflammation goes on, the redness and swelling may more or less involve the whole lid, so that the eye becomes completely closed. In a few days matter forms, and shows itself at the summit of the stye; the cuticle gives way, pus and a small slough of areolar tissue escape; and then the redness and swelling subside, and the lid soon assumes its former appearance.

Scrofulous and delicate children are the usual subjects of styes, and they are comparatively rare in adults. Attention to the state of the bowels, carefully regulated diet, and the use of tonics, comprise the general treatment. Locally, warm water dressings are greatly to be preferred to poultices, which are apt to irritate the skin. The stye should never be rubbed or squeezed; and no incision is necessary, except, perhaps, a slight puncture through the cuticle when the pus is pointing.

Abscess sometimes occurs in the Meibomian follicles. These organs pour out upon the edges of the lids a greasy secretion, which prevents the tears running over, and causes them to flow onwards to the puncta. Sometimes a follicle becomes obstructed at the orifice, and the retained secretion forms a minute solid granule looking, when extracted, like a little grain of sand. If it projects sufficiently to touch the globe, a slight irritation is produced until the granule is removed.

If, however, the solidified secretion cannot in this way escape through the orifice of the follicle, it causes irritation, and at last a small abscess in the follicle itself. The lower lid is commonly the seat of these abscesses. They commence with a small patch of vascularity in the palpebral conjunctiva, a short distance from the free border of the tarsus, and gradually a yellow dot of pus forms in the centre of the vascular patch. If the conjunctiva at this point be punctured with a lancet, and a small scoop be introduced, the cause of the suppuration, a little nodule of stearine, about the size of a poppy-seed; may usually be turned out, and then all irritation subsides.

Tinea ciliaris,—termed also *ophthalmia tarsi*, *psorophthalmia*, *tinea palpebrarum*, &c.,—is one of the most common and troublesome diseases of the lids. It is too often neglected during the early stage, when alone it is really curable, and the surgeon is probably consulted for the first time when many of the hair-bulbs have already been irreparably destroyed, and the remaining hairs are misplaced and inverted, constituting the state called *trichiasis*. This term is frequently employed as if synonymous with entropion, but it ought properly to be restricted to mean displacement of the *hairs* themselves, while entropion signifies a turning-in of the *lid*.

Tinea ciliaris is seldom seen in its early pustular form; for the little pustules at the roots of the eyelashes soon break, and the discharge exuded from them dries into crusts, which cling about the hairs, matting them together, and sometimes almost concealing them from view. *Tinea ciliaris*, if allowed to go on unchecked, gradually destroys the tissues which secrete the hairs; and when the disease has thus exhausted itself, and the last crusts have fallen off, the tarsi, instead of presenting sharply-bevelled edges, appear rounded off, the skin and conjunctiva being gradually blended together into one smooth, red, shining cicatrix, in which neither cilia nor Meibomian orifices can be traced. Very often the puncta also become obliterated, and the tears consequently run over the cheeks, causing irritability and blinking of the lids. This is the condition to which the term *lippitudo* should be restricted; *tinea ciliaris* being understood to mean that state in which active disease at the root of the eyelashes is still going on.

In the treatment of *tinea ciliaris*, the chief difficulty arises from the age of the patients. Daily attention is required, to prevent the accumulation of crusts, which should be carefully washed off night and morning. Patients often derive but little benefit from the remedies prescribed, in consequence of this regular cleansing being neglected. It is useless to apply ointments anywhere except upon the very surface of the minute sores at the roots of the hairs; and if the latter are kept closely cut with scissors, the application of ointments, and the prevention of crusts, are greatly facilitated. Of course, this cutting of the eyelashes requires to be done by the surgeon himself, and the ointment should be neatly applied with a pencil. When cases cannot be thoroughly looked after, it is perhaps better to prescribe lotions, as they can hardly fail to reach the seat of disease. Ung. hydr. nitratis, ung. hydr. nitricooxydi, and ung. zinci oxydi, sufficiently diluted with vaseline, are the best ointments. The acetate of lead may be used as a lotion, in the proportion of from two to four grains in the ounce of distilled water.

The worst forms of *lippitudo* may often be greatly relieved by slitting up the canaliculi in the manner described at page 112. By this means the overflow of tears is checked, and this of itself is an immense comfort to the patient; while, at the same time, the tendency to ectropion, which long-continued *lippitudo* often induces, is considerably diminished.

Phtheiriasis.—Among the irritable conditions of the eyelids, I may here notice that arising from the presence of lice. These creatures are 'crab-lice' (*phthirus*), a species quite distinct from that which infests the scalp (*pediculus*). They thrust their heads into the skin at the roots of the cilia, and by means of the sharp claws with which all their legs, except the first pair, are provided, hold on so firmly, that they cannot be dislodged without great difficulty.

Phtheiriasis of the eyelids is an extremely rare affection, at least in this country. On superficial examination, the cases are very similar to those of *tinea ciliaris*. The eyelashes present a powdery appearance, and their roots seem to be clogged with yellowish-gray and brown crusts. But by careful scrutiny of these supposed crusts, the movements of the lice may be detected; and the powdery appearance of the cilia is owing to their being clogged with the exuviae of the creatures, and dried sanies from the wounds they have inflicted. The insects may speedily be destroyed by thoroughly smearing into the roots of the eyelashes the white precipitate ointment (ung. hydrarg. ammonio-chloridi).

MORBID GROWTHS OF THE LIDS.

The following are the more common swellings which appear in or upon the lids.

Cysts, of two distinct kinds. These of the first kind, extremely common, are met with both in the upper and the lower lid (*Encysted tarsal tumour*, Tyrrell; *Chalazion*, Mackenzie); the others are found almost invariably at one spot, namely, just over the external angular process of the frontal bone, to the periosteum of which they are attached.

Warts are sometimes found on the lids, differing in no respect from those on other parts of the body.

Nævi materni, resembling those of other parts.

1. *Cysts* of the lids are met with at all ages. They may exist singly, or several may appear together, coming successively to their full growth. The skin over them is quite unchanged, so that, when small, they are hardly recognisable except by the touch. They feel like half a hemp-seed or half a pea fixed by the flat side to the tarsal cartilage, and presenting a convexity towards the skin, which may be freely moved over them. They rarely exceed the size of a pea, except when suppuration has taken place within them.

If the lid be everted, the position of the cyst is recognised by a thinning of the tarsal cartilage, forming a dusky spot, around which the conjunctiva is reddened. These cysts may remain of a moderate size during life, without causing any inconvenience; but sometimes they suddenly inflame and become enlarged, the skin over them reddens and at last gives way, a small quantity of pus escapes, and afterwards a thin sanies continues to ooze from the aperture. But more commonly the pus makes its way through the palpebral conjunctiva, and then a little red fungous mass gradually protrudes, which, by the continual pressure of the eyeball, becomes flattened out into a mushroom shape.

When these cysts are so small as to escape ordinary observation, they require no treatment; but, if they become so large as to be unsightly, and, still more, if they inflame and suppurate, they must be treated in the following way. The lid being everted, a crucial wound is made through the conjunctiva into the cavity of the cyst. If the inflammation has been acute, pus escapes, otherwise a little serum. A scooped probe passed into the cavity, and twirled about in various directions, brings out the contents, which have a jelly-like appearance. Blood then fills the cyst, and makes it as large as it was before the incision. The patient, however, may be assured that this swelling will gradually subside. To prevent premature closing of the wound, and refilling of the cyst, the probe should be used in the way just described every third day for about a fortnight. The walls of the cyst come together, and ultimately form a slight thickening in the lid, just perceptible by the finger applied to the skin.

Fibrous cysts, varying in size from that of a large pea to that of a hazel nut, and containing sebaceous matter and hairs, are almost invariably confined to one situation, namely, just over the external angular process of the frontal bone. They appear to be congenital; at least, I have seen them of considerable size in infants four or five months old. The skin over the cyst retains its natural appearance, and it is only on account of the unsightliness that the surgeon is consulted.

In dissecting out the cyst, which is the only mode of treatment, great care is requisite to avoid cutting into it: and especially while the cyst is being separated from the periosteum, to which it always adheres pretty closely. The cavity is lined by a smooth membrane, and is filled with white greasy material interspersed with loose hairs. In a cyst removed by one of my colleagues from an infant five months old, these hairs were still growing from the lining membrane. It seems that, in the course of years, these hairs may attain a considerable size, while the fatty material degenerates into oil. Such was the case in a very large cyst which I removed from a woman between thirty and forty. The skin had become so much thinned as to have assumed a dusky hue; and in endeavouring to dissect out the cyst I punctured it, and there escaped a quantity of perfectly clear yellow oil. There remained within

the cavity only some detached black hairs, loosely curled together, and as strong as those of the head.

2. *Molluscum* attacks children in the form of small, white, rounded bodies, scattered over the lids, the *alae nasi*, and about the corners of the mouth. When very small, these bodies are slightly reddish; but when as large as a pea, they are white, and exhibit at the apex a minute opening through which a milky fluid exudes on pressure. The readiest way to get rid of these unsightly masses is to split them all through with a lancet, and then to nip out with the nails the contents of each. The mass, when pressed out, looks almost like a fragment of parotid gland.

3. *Warts* may be snipped off with scissors.

4. *Nævi* of the lids differ in no respect from those met with in other parts of the body; but they require more careful and discriminating treatment, on account of the importance of ~~providing~~, as much as possible, any considerable loss of skin; a large cicatrix being not only in itself unsightly, but likely, by its contraction, to cause distortion of the lid. Subcutaneous ligature, therefore, or the introduction of probes coated with fused nitrate of silver, must be preferred to including any portions of skin within a ligature, or extensively destroying it with escharotics.

I have seen injections of alum cause sloughing of the lids and great subsequent deformity; and such a result might follow the injection of any similar fluid into the loose areolar tissue of the part, unless some contrivance can be used to restrain the fluid within proper limits.

In the following case an injection of tannin proved successful.

A young lady was brought to me with a *nævus* on the upper lid, the size of a small hazel-nut. I was informed it had already been twice operated on by the introduction of threads steeped in nitric acid, and much inflammation and sloughing had ensued, as was proved by a considerable cicatrix of the skin near the outer canthus. The apex of the swelling was on the free margin of the lid, on everting which, a small bunch of veins, about the size of a barley-corn, was seen projecting through the tarsal cartilage, only covered by conjunctiva. The *nævus* seemed to be formed almost wholly by veins, the larger trunks of which could be felt through the skin, as they emerged below the superciliary ridge.

Having enclosed the whole upper lid in a 'ring forceps,' I could completely isolate the *nævus* from its parent veins, and I then punctured it with a very small narrow knife (Haye's needle-knife), and cut up its tissue subcutaneously. Being emptied of its blood, the *nævus* collapsed; and I next, with a fine syringe, threw in a few drops of a saturated solution of tannic acid. After a short pause, I relaxed the pressure of the ring forceps, and so allowed the returning blood to mingle with the injected fluid.

The subsequent inflammation produced a great deal of swelling and hardness of the lid; but the only slough was a mass about the size of a small pea, which made its way out at the little wound. The final result was complete obliteration of the *nævus*.

Galvano-puncture is a very useful method of treatment.

Carcinoma rarely commences in the lids, although it may spread to them from other parts. Should it be already far advanced when first brought under the surgeon's notice, extirpation would hardly be attempted. Small, hard, suspicious growths at the margin of the tarsus may be removed by ~~excising~~ a wedge-shaped portion of the lid on which they grow, and then uniting the wound with sutures.

The *epithelial* form chiefly attacks the skin over the lacrymal sac, and from that point extends over the nasal and superior maxillary bones, having the appearance of a shallow pale ulcer, with an irregular outline and uneven borders, and with a scarcely perceptible quantity of secretion. Chloride of zinc, made into a paste, and applied over the entire surface of the sore, so as to include its edges, will sometimes very effectually destroy the morbid growth, and it may be reapplied whenever any part of the border of the sore begins to exhibit fresh activity. Preferably the morbid tissue may be excised or removed with a sharp scoop before the application of the escharotic.

INJURIES OF THE LIDS.

Ecchymosis.—An effusion of blood into the areolar tissue of the lids, popularly termed 'a black eye,' is commonly the result of a blow; but it may arise from other causes, as, for instance, from the unskilful employment of leeches. The sufferer is always most anxious to get rid of the ecchymosis as quickly as possible; and I know of no treatment so efficacious as that handed down by the traditions of pugilism, consisting in the application of a poultice formed of the freshly-scraped root of the 'black bryony' (*tamus communis*), mixed with a due proportion of linseed-meal or bread-crumbs. Poultices of this kind produce a stinging sensation in the skin, and, if regularly applied for a day or two, seldom fail in effecting a complete absorption of the effused blood. Where this is not at hand, a compress dipped in Goulard water may be put on.

Emphysema.—This, like ecchymosis, is usually the result of a blow with the fist, which fractures some of the thin brittle bones, such as the lacrymal or ethmoid, forming the inner wall of the orbit. If, shortly after such an injury, the patient blows his nose, the eyelids suddenly puff up, so that he is unable to separate them. On pressing the part with the fingers, we at once perceive the peculiar crackling caused by the presence of air in areolar tissue. If the patient abstain from blowing his nose, the effused air soon becomes dispersed, and the swelling disappears.

Wounds of the lids have already been considered.¹ They are to be treated on the common principles of surgery which apply to other regions. The careful surgeon would naturally be alive to the importance of obtaining the nicest adaptation of cut surfaces in parts so open to observation. The yielding nature of the skin of the lids, and its plentiful supply of blood, offer peculiar facilities for effecting close and smooth union of wounds by means of fine sutures, in applying which the greatest care must be taken to avoid any irregularity and puckering of the cut edges.

CHAPTER XIV.

DISEASE OF STRUCTURES WITHIN THE ORBIT.

STRUCTURES very dissimilar, as regards their nature and functions, are grouped together in the present chapter; but they are all more or less concerned in supporting or imparting motion to the eyeball. The various morbid growths within the orbit, which cause displacement or impair the mobility of the organ, are also here briefly noticed.

PROTRUSION OF THE EYEBALL.

(*Proptosis oculi*; *Ophthalmoptosis*; *Exophthalmos*.)

Various causes may induce an unnatural prominence of the eyeball; but cases are sometimes met with in which this prominence seems of itself to form the whole morbid condition. The eyes have a remarkably staring expression, and look as if they were much too large for their sockets. The tarsi can be brought into contact; the eyes themselves move freely in all directions, and sight is unaffected. The equal amount of prominence in both eyes, and their unimpaired functions, at once remove any suspicion of orbital tumour.

Women of feeble and hysterical constitution, and those affected with bronchocele, are the usual subjects of this deformity, the cause of which is very obscure. Atony of the recti muscles has been suggested; and no doubt a weakened state of these muscles might produce a certain amount of prominence of the eye, but would be incompatible with its free motion. I have never seen any cure or benefit result from

¹ See INJURIES OF THE FACE.

treatment in these cases of proptosis. The reader is referred to the works of Graves and Bercow for good descriptions of this affection. The want of arterial tone which usually accompanies this form of proptosis suggests the use of iron and strychnine, and these sometimes appear to influence it beneficially.

Dislocation of the eyeball from the socket is an accident we often hear of, but, I need hardly say, that without rupture of the optic nerve the eye cannot be thrust upon the cheek, where it so often figures in the exaggerated accounts of patients. What really takes place is, probably, the lodgment of the upper lid behind the greatest convexity of the globe. I have seen this accident occur when a surgeon, anxious to explore the upper surface of the sclerotic, in search of a foreign body, or for some other cause, has too forcibly thrust back the upper lid. The tarsus, being forced beyond the summit of the eyeball, has suddenly slipped backwards, and become fast locked behind it. A wire elevator or a bent probe will enable the surgeon to lift up the tarsus and restore it to its place.

Hydatids, cancerous growths, and exostoses, by encroaching upon the cavity of the orbit, all give rise to gradual displacement of the eyeball. As this displacement increases, the movements of the eyeball become more and more limited, until at last it remains quite fixed.

It requires much careful investigation into the history of the case to enable the surgeon to determine the nature of the morbid growth. Exostoses are the slowest, and encephaloid tumours the most rapid in their progress. It is sometimes possible to pass in the tip of the little finger between the globe and the anterior edge of the orbit, and thus partially to explore the surface of the tumour. Cysts are recognised by a feeling of elasticity and fluctuation; and in doubtful cases a puncture with a fine trocar will sometimes reveal the true nature of the mass.

The removal of morbid growths from the orbit requires the utmost care, to avoid inflicting injury upon the eye itself or the optic nerve; and, before attempting such an operation, the surgeon should be well convinced that the mass is limited to the orbit, and has not extended into it from the cavity of the skull.

Abscess in the orbit occurs as a result of injury, such as the entrance of a foreign body; or it sometimes seems to be the effect of a chill. In a less acute form we meet with it as a sequela of fever and erysipelas. The suppuration is ushered in with rigors and depression; the conjunctiva and areolar tissue of the globe are red and infiltrated, the lids swollen and livid; the eyeball becomes prominent and immovable; and at length fluctuation can be detected by the finger passed in between the lids and the globe. The rapidity with which these symptoms follow each other would serve to distinguish suppuration from the growth of a tumour. Until fluctuation occurs, the existence of pus in the areolar tissue of the orbit is very obscure; the deep exploratory punctures which some surgical writers advise to be made between the eyelids and the globe are not free from risk, considering how closely the eyeball is surrounded with muscles and nerves, which random incisions would endanger; but a careful surgeon may sometimes succeed in safely opening a deep orbital abscess, and timely evacuation of the abscess is of the utmost importance to the safety of the eyeball.

Chronic abscess in the orbit is commonly the result of caries or necrosis; and the denuded bone will be felt by introducing a probe through the opening by which the pus has been evacuated.

Orbital abscess, even of the acute and so-called phlegmonous kind, so commonly occurs in depressed and feeble subjects, that light and nutritious diet, with a due proportion of stimulants, will be indicated instead of abstinence and leeches. The bowels should be rapidly unloaded, and then narcotics given in doses just sufficient to soothe the pain and induce sleep. Bark and ammonia, wine and other tonics, will often be needed in increased quantities during the free suppuration, which not uncommonly follows the opening of the abscess. Warm water-dressing will be throughout the best local application.

AFFECTIONS OF ORBITAL NERVES.

The eyeball and its appendages derive their sensibility from branches of the ophthalmic division of the *fifth* nerve, which not only endows these parts with feeling, but also so far influences their blood-supply that total anæsthesia of the nerve is followed, sooner or later, by deranged nutrition of the cornea, and by other phenomena generally described as 'inflammatory.' The value of this as evidence of a trophic influence of the fifth nerve over the eyeball is lessened by the experiments of Snellen described in the *Archiv. für Ophthal.*

These phenomena have been already noticed in the Chapter treating of Diseases of the Cornea; and at present we may confine our attention to those motory nerves which supply the muscles of the lids and globe,—namely, the third, fourth, sixth, and 'portio dura' of the seventh, or facial.

The orbicularis palpebrarum is supplied by the last-named nerve, and when this is paralysed, the tarsi can no longer be brought into contact. If the patient is told to shut the eye, the lids remain immovable, if the paralysis is complete; or if it be only partial, a slight attempt at closure takes place. At the same time the eyeball is rolled upwards by the action of the superior rectus, as if seeking in that way the shelter of the upper lid. Sometimes the branch supplying the orbicularis palpebrarum is alone paralysed, but more frequently this is affected in common with the other facial muscles.

The orbital nerves, it will be remembered, are distributed as follows: the third to the levator palpebræ, the superior, inferior, and internal recti, and inferior oblique muscles; and also to the iris, through the medium of the ophthalmic ganglion. The fourth nerve supplies the superior oblique, and the sixth the external rectus.

It is not necessary that all the muscles supplied by one of these nerves should be affected at the same time, or to the same extent; but for the sake of illustration we will assume cases in which the various nerves have wholly lost their motory function.

The following are the symptoms of paralysis of the *third* nerve. The upper lid hangs motionless, and is in contact with the lower one (*ptosis*). On lifting it we find the globe abducted, so that the cornea is turned towards the temple. The patient can direct the eye still further outwards, but neither inwards, upwards, nor downwards. The pupil is dilated and fixed, and on that account distinct vision, for near objects, is impaired, although the optic nerve and retina may be wholly unaffected. By looking through a small aperture vision which diminishes the dispersion consequent on abeyance of accommodation, becomes improved. If the patient looks with both eyes at objects placed on that side of him towards which the affected eye is abducted, they appear single; while objects in the other direction appear double. If all the branches of the third nerve are paralysed, the inferior oblique muscle of course ceases to act, and the superior oblique having no antagonist rotates the globe on its antero-posterior axis, and hence vertical objects seen with the affected eye appear oblique.

If the *sixth* nerve alone be paralysed, the eye is turned inwards. This inversion can be increased at will, and the eye can be freely moved upwards and downwards; the pupil is of natural size and active, and the upper lid retains its motions unimpaired. If the patient looks at objects on that side towards which the eye is inverted, they appear single; but objects in the other direction are double.

Paralysis of the *fourth* nerve is much less common than either of the two forms already mentioned, and, on account of the very slight change it causes in the position of the eye, is very difficult of detection. The paralysis is chiefly to be recognised by its subjective phenomena. If, for instance, the patient with both eyes open fixes his attention on some straight line on the ground, as the edge of a gravel-walk, or the curb-stone of a foot-pavement, he sees two lines, one in its real position, and the other forming with it a more or less acute angle. If with both eyes he looks at a near object, such as a large capital letter, at such an angle that it appears double, the image perceived by the affected eye will incline from the perpendicular, and its

lines cannot be brought parallel to those seen by the sound eye, unless the patient inclines his head to one side. The letter T or a +, as containing right angles, are good forms for testing the defect.

The *treatment* of paralytic affections of the orbital nerves must be based on a careful investigation into the symptoms of each individual case, for the causes of paralysis may be very various. Slow, and eventually total, paralysis of one or all the nerves which enter the orbit may depend upon chronic changes in the brain itself, or the dura mater, the growth of tumours, disease of bone, &c. Sudden paralysis may follow apoplectic effusion or other injury to the cerebral structure, or may depend upon rheumatic inflammation of the fibrous tissues immediately surrounding and investing the nervous trunks.

Of course the prognosis would vary greatly accordingly as one or another of these causes had induced the paralysis. In the case of chronic brain disease, or the growth of intracranial tumours, the treatment could be only palliative. The probability of recovery in cases of apoplexy would depend upon the extent of the extravasation.

If one or more of the orbital nerves were suddenly paralysed, and at the same time other parts of the body were affected with loss of motory power, while the brain itself gave evidences of its whole circulation being disturbed, there would be comparatively little chance of the orbital muscles recovering their function. But if the paralysis were so completely limited to one of the orbital nerves as to render it probable that only some minute vessel in the course of the motor-tract had given way, and had involved the adjacent brain-fibres, the absence of all other cerebral symptoms would warrant the hope that considerable improvement, or even complete recovery, might take place.

By far the most hopeful cases are those where the paralysis of the orbital nerve can be traced to rheumatism; since a well-directed treatment of the general rheumatic diathesis will, in all probability, restore the affected nerve to a healthy condition. A large number of orbital palsies are due to syphilis.

STRABISMUS.

The various forms of mal-position of the eyeball just noticed, depending upon more or less sudden paralysis of the ocular muscles, might, according to strict etymology, be classed under *strabismus*, but the term is here restricted to those chronic cases in which habitual mal-position results from irregular action of either the internal or external rectus. The deformity may be defined as a faulty position of the eyes, whereby a separate image falls upon each macula lutea, when the patient endeavours to direct both eyes to one object at the same time.

Strabismus may be either *convergent* or *divergent*. In the former case the eyes, or eyes, will be directed towards the nose: in the latter case towards the temple. The strabismus is termed 'single' if one eye only is misplaced, and 'double' when both eyes converge or diverge. In many cases which ordinarily appear as double strabismus, one eye becomes perfectly straight whenever the patient fixes his attention on an object; and the eye which thus for a time acquires a normal position will be found to have the stronger powers of vision.

In other instances of double strabismus both eyes maintain their inverted position, even while the patient is intently observing an object; but if the surgeon suddenly closes one of these convergent eyes, the other at once becomes straight, resuming its inversion as soon as the other eye is opened.

Donders has shown that in the great majority of instances convergent strabismus is associated with hypermetropia; and the divergent form with myopia. Divergent strabismus however is rare, except as a consequence of considerable loss of sight in one eye, persisting for several years.

The *causes* of strabismus are very various. When existing only to a slight degree, coming on only occasionally, and alternating from one eye to the other, it will sometimes be found due to intestinal irritation, such as that arising from worms. In other cases, it may be traced to the temporary cerebral disturbance induced by

teething, or to the more persistent form which attends hydrocephalus. An opacity near the centre of the cornea will sometimes cause an eye gradually to turn inwards, through a sort of instinctive effort of the organ to bring a clear portion of the cornea into use.

The *treatment* of strabismus, as will be evident from what I have just said as to its causes, must vary according to circumstances. The removal of intestinal irritation; the use of tonics; the employment of convex glasses, to correct extreme hypermetropia;—these, and many other means, may be useful to control strabismus which is only temporary, or which arises from peculiarity in the visual focus of the eyes. In every case a careful ophthalmoscopic examination is the first duty of the surgeon; and he should also take every possible care to ascertain that no organic disease exists in the brain or orbital nerves, and that there is no tumour in the orbit mechanically hindering the movements of the eye.

It is of no less importance to distinguish the strabismus due to palsy of the rectus externus from that due to hypermetropia. In paralytic squint the secondary squint is greater than the primary, and the mobility of the squinting eye is restricted. In hypermetropic squint the primary and secondary squints are equal in amount, and the mobility of the eye is not lessened.

The *operation* for the cure of strabismus consists in the division of the muscle, which, in consequence of shortening, or too great preponderance in contractile power, is permanently drawing the eye either inwards or outwards. Division of the internal rectus, when first introduced, was performed in the following way. The lids being held apart by an assistant, a small sharp hook was stuck into the sclerotic, close to the inner margin of the cornea, so as to fix the eyeball and draw it outwards. Then the surgeon, raising with a forceps a fold of conjunctiva midway between the cornea and plica semilunaris, divided it vertically with scissors, snipped through the sub-conjunctival tissue covering the tendon of the muscle, passed under it a blunt hook or director, and upon this divided with scissors, or with some kind of knife, either the tendon itself or the adjacent muscular portion of the rectus internus.

As in all other instances of manual surgery, the apparatus for performing this operation gradually became simplified. The spring speculum superseded the elevators held by an assistant; the sharp hook for fixing the globe was laid aside; and it was found that all the cutting could be done by scissors alone. The curious little knives, in every variety of form, which had been invented for dividing the muscle, are now for the most part forgotten; as are also the unseemly disputes about priority in trifling discoveries, and the exaggerated accounts of the uniform success which was stated to have attended the practice of certain strabismus operators.

The defects of this earliest form of operation were a too great separation of the ocular conjunctiva, inducing a subsequent retraction of the semilunar fold, and an over-weakening, amounting sometimes to utter loss of action, in the divided muscle.

We still occasionally meet with a fixed and leering eye which recalls the period of the first introduction of the operation in 1840; when every tyro fancied himself competent to cure a squint.

The deformity arising from retraction of the semilunar fold is now in a great measure obviated by sub-conjunctival division of the muscle. The lids are kept asunder with a spring speculum; and an assistant draws aside the globe, by nipping up with the forceps a little fold of conjunctiva and fascia near the margin of the cornea, at the opposite side to that on which the muscle is to be divided. Supposing the internal rectus to be chosen for operation, the surgeon, with scissors, divides the ocular conjunctiva horizontally, on a level with the lower edge of the cornea, and extends the incision towards the semilunar fold. Then he snips through the sub-conjunctival tissue, and having clearly exposed the sclerotic, slides upwards, between it and the rectus, a curved director. This serves to raise the muscle and make its fibres tense, and then with scissors the muscle is carefully cut through, close to its insertion into the sclerotic. This section of the muscle cannot be completed at a single stroke, but requires repeated use of the scissors, so that no fibres may be left undivided.

While this sub-conjunctival operation through a horizontal external wound obviates the retraction of the semilunar fold, it involves the risk of an imperfect division of the muscle, which is not exposed to the view of the surgeon. A careful exploration with the blunt hook or director must be made to detect any undivided fibres, before the spring speculum is finally withdrawn.

Graefe divided the conjunctiva a little below the equator of the globe and a few lines from the cornea, almost over the insertion of the tendon; exposed the sclerotic just enough to pass a curved blunt hook beneath the tendon, which is then snipped through close to its sclerotic attachment; care being taken that the hook, which is sharply curved, is not allowed to perforate the tendon, but is passed well under it. In this operation the tendon is not brought into view.

In dividing the *external* rectus, it must be borne in mind that the muscle is broader than the internal rectus, and is also inserted farther from the corneal margin.

Most cases of strabismus require the division of each internal rectus, even when the inversion of the better eye is but slight in comparison with the other. Instances, however, occur in which the inversion is wholly confined to one eye: and in such a case the faulty eye may alone be operated upon.

No absolute rule can be laid down as to the use of chloroform in strabismus operations. In most cases it will be found necessary: but where patients are fitted by age, intelligence and self-command to undergo the operation without it, the doubt which sometimes exists as to whether the muscle has been effectually divided can be at once solved, by directing the patient to attempt inversion of the eye; a test we are unable to employ when insensibility has been induced.

When, in searching for the muscle, the subconjunctival areolar tissue has been largely separated, it becomes infiltrated with blood, and forms a little prominence in the wound. The blinking of the lids gradually moulds this into a small button-shaped excrescence, attached by a narrow pedicle, which may be snipped through some weeks after the operation.

REMOVAL OF THE EYEBALL.

Certain diseased conditions of the globe may require a portion of it to be removed, while in other cases its tissues may be so extensively involved, and so much constitutional disturbance may in consequence arise, as to render necessary the total extirpation of the whole organ.

In non-malignant cases this operation is usually undertaken with a prospect of the patient afterwards wearing an artificial eye, and it therefore becomes important to consider whether a total or a partial extirpation will be best adapted to the end in view.

The enlargements which call for removal, on account of the deformity they occasion, are chiefly staphylomatous projections of the cornea or the sclerotic. Under the former term are commonly included projections which have really little or no corneal tissues within them, being formed of the iris coated over with fibrous tissue, after the true cornea has been partially or wholly destroyed by ulceration or sloughing. The sclerotic staphylomata, as they are called, are produced by gradual thinning and distension of the weakened fibres of the part from accumulation of aqueous humour or of serum. In some of the latter cases the eyeball acquires a very large size, and is extremely unsightly, on account of the dark leaden-coloured projections of the sclerotic, and the large tortuous veins which run over it. When the cornea has been extensively destroyed by sloughing or ulceration, it very commonly happens that the lens escapes through the breach; when this does not take place, the lens frequently becomes filled with a deposit of phosphate of lime, and this earthy mass, by pressing against the ciliary processes and iris, often causes severe neuralgia. In excising a staphyloma, therefore, the opening should be made sufficiently large to allow the lens, if still existing, to escape.

In operating, the lids must be held apart with a spring speculum or the fingers of an assistant. The surgeon then passes a cataract-knife through the staphyloma, and forms a flap, which he seizes with a forceps, and removes with a second stroke of the knife; if the lens presents at the opening, it is to be quickly tilted out with a scoop, and then the lids are instantly to be closed, and a cold sponge applied firmly over them. This immediate pressure is the most likely means for preventing hæmorrhage from the enlarged choroidal vessels, which sometimes give way the moment the fluid contents of the globe have escaped. Moderate pressure should be kept up until the risk of bleeding has gone by, and then water-dressing will be the only application required till the parts are healed. The portion of the globe left after the excision of a staphyloma gradually shrinks to a nodule, and as soon as this has ceased to be tender, an artificial eye may be applied.

If, in consequence of the sudden removal of the pressure which the accumulated fluids of the globe had been exerting on the choroidal and retinal vessels, the latter give way, and blood fills and distends the cavity of the sclerotic, extreme pain is the result, and it may even be thought desirable at once to extirpate all that remains of the globe, with the view of preventing future suffering. With the object of obtaining a better stump on which to wear an artificial eye, Critchett modified the operation for staphyloma as follows. He passed severed curved needles armed with threads through the sclerotic, above the base of the staphyloma, quite into the vitreous chamber, and brought out their points at the opposite side of the projection. He then cut away an elliptical portion from the front of the mass, drew the ligatures quite through, and tied them in knots, which then lay just across the line of the closed incision.¹

Total extirpation of the eyeball.—This operation, except when malignant disease exists, should never be resorted to, so long as any sight remains in the organ; unless it should be so irritable as to lead the surgeon to fear that, by sparing it, the sight of the fellow eye may be endangered. Restricted within due limits, and not undertaken through a morbid love of operating, extirpation of the eyeball is a ready means of relieving patients whose whole system may have become impaired by long-continued neuralgia, arising from distension of the globe, or lodgment of foreign bodies within its cavity.

The operation, which was formerly effected by scooping out all the contents of the orbit, has been greatly simplified by the adoption of Bonnet's method, in which the globe alone is removed. A circular incision is made through the conjunctiva and ocular fascia, and then each muscle of the eyeball is successively divided close to its insertion, and the optic nerve just before it pierces the sclerotic.

The operation is usually performed by raising with a hook all the tendons of the ocular muscles, and dividing them before cutting through the optic nerve.

I prefer the following plan, as simpler and more rapid. Having inserted the spring speculum between the lids, and made with curved scissors the usual circular incision of the conjunctiva, I grasp the external rectus and its surrounding tissue with a forceps, and snip them through; an assistant at once seizes the cut tendon close to its insertion, and draws the eye inwards. By sliding one blade of the scissors under the superior oblique and rectus muscle, they can be divided, and then the inferior rectus. The optic nerve is next snipped through, and the globe starts forward. A few strokes of the scissors divide the inferior oblique, internal rectus, vessels, and bands of areolar tissue, and the operation is completed. Cold water and exposure to the air suffice to arrest the bleeding, and then water-dressing is all that is required.

USE OF CHLOROFORM IN OPHTHALMIC SURGERY.

We may regard chloroform under two aspects: as saving the patient from pain, and as facilitating the manipulations of the surgeon. Now it is well known that

DISEASES AND INJURIES OF THE EAR.

In the present article the natural division of diseases of the ear into those of the external, middle, and internal respectively, will be followed for the sake of convenience in describing them; but it will be observed that there are many abnormal conditions of the auditory apparatus which do not admit of so precise a definition; for, although in many diseases it happens that at first only one portion of the ear is affected, in the later stages of some affections two, and sometimes the three, divisions become involved in turn. This observation will be found to be true in the case of polypus and other morbid growths, acute inflammations which accompany the exanthematous fevers, disease of the temporal bone, syphilitic affections, and others which might be enumerated.

EXAMINATION OF THE EAR.

For a complete examination of the ear it is necessary that a threefold method should be employed. In the first part, the external canal and tympanic membrane are brought under observation; in the second, the degree of patency or obstruction of the Eustachian tube, and the normal or undue secretion within the tympanum, are estimated; by the third, abnormalities in the conduction or perception of sonorous vibrations are determined.

FIG. 6.—Hand-mirror.

FIG. 7.—Ear Specula.

It is agreed amongst all practised observers that the external canal and tympanic membrane can be most satisfactorily examined by reflecting light from a concave perforated hand-mirror of eight-inch focus down a funnel-shaped speculum of the kind known as Gruber's; owing to the great variety in the calibre of the meatus, several sizes should be at hand. The patient, who must be seated close to a window, should have his head turned away from the light.

The speculum being then introduced, by moving it gently in different directions every part of the canal and membrane may be brought into view. Such movements are necessary on account of the curvature of the meatus, which winds at first a little downwards, then backwards, and slightly upwards, as far as the middle portion, beyond which it curves downwards until the tympanic membrane is reached.

If any manipulation or operative proceeding is required, the mirror fixed on the forehead by a band round the head must be used instead of the hand reflector. When bright diffused daylight is not obtainable, gaslight from an Argand burner affords perhaps the most convenient substitute. In passing, it may be remarked that the use of an ear speculum, being rather to afford a straight tunnel for light than to dilate the auditory canal (except under certain unusual conditions), it should not exceed altogether in length one and a half inches; and, as it is desirable that the tubular portion should occupy as little space as possible in the canal, silver specula are better than those made of vulcanite.

The more or less perfect patency of the Eustachian tube may be diagnosed by the normal or abnormal appearances on the membrane which will be described under **AFFECTIONS OF THE MIDDLE EAR.**

The method of inflating the middle ear now in constant use is described by its inventor, Dr. Adam Politzer, as follows:—‘The patient, being seated, takes some water into his mouth, to be swallowed at a given signal. The surgeon, placing himself

FIG 8.—Mirror with frontal band.

conveniently to the right of the patient, grasps with his right hand an india-rubber bag, about as large as the two fists, and introduces the nozzle of a somewhat curved hard india-rubber tube, moveably connected with it, about half an inch into the nostril, so that its concavity is in contact with the floor of the nares. The signal is given to swallow; both are at the same time closed air-tight over the instrument with the thumb and forefinger of the left hand, and, by a forcible pressure of the right hand, the air is driven out of the bag into the now shut nasal cavity.’

Whilst inflation of the middle ear is thus practised, a piece of india-rubber tubing, of about three feet in length, should connect the ear of the surgeon with that of the patient under examination. Through this, the air as it passes into the tympanum may be heard to impinge upon the membrane (the patient is conscious of it so doing), and the state of the tympanic cavity in reference to secretion within it may be estimated.

Of all the various tests for hearing which have from time to time been introduced, owing to the constant character of the notes which are produced, they are found to be serviceable only so far as they are a means of indicating changes in hearing from time to time. In order to obtain a comprehensive knowledge of the hearing possessed by a patient, nothing is equal to the voice, used at various pitches, and at varying distances. Each ear must be tried in turn whilst the other is effectually stopped, and the voice must come from directly behind the patient. If he can see the surgeon, the test is of course valueless, as he unconsciously aids the hearing by reading from the lips of the speaker. With adults they must repeat verbatim what is said, and with children the examination must be conducted by question and answer; or, still

better, the child must not be considered to have heard till he has performed some movement or action at the request of the speaker.

To measure accurately a child's hearing, considerable patience is necessary, as when the deafness is extreme, children are so sensitive to vibration, that feeling is often mistaken for hearing. This applies especially in the case of absolutely deaf children, who will feel a piano playing, or a step into a room, so well as to deceive any one who is not experienced in their ways.

In the examination of adults, when the hearing has been generally estimated, the manner in which a vibrating tuning-fork is heard (when placed on the head) through the cranial bones, taken in conjunction with the examination of the external

FIG. 9.—Politzer's method of inflating the Tympana.

and middle ear, will enable the observer to appreciate in what degree respectively the conduction or the perception of sound is faulty. In some nervous affections the power of hearing very high notes should be tested by a Galton's whistle; but the details of these matters will be discussed more fully with the diseases on which they have especial bearing.

THE EXTERNAL EAR.

Malformations of the external ear are with very rare exceptions associated with arrested development in the middle and inner ears. The whole subject is interesting rather from a physiological than a surgical point of view, except in so far that it often rests with the surgeon to determine in early life to what extent, if any, a child with a deformity of this kind is possessed of hearing power. The question as to what method of education should be pursued with a child must be decided by this. A rudimentary lobe often takes the place of the auricle, and the appearance of the lobe varies very much. Sometimes it is nothing more than a mere fold of integument; or there may be two, three, or even more, such appendages. It is noticeable that in almost all cases the position which should be occupied by the orifice of the meatus is marked with a slight opening just sufficient to admit for a short distance (perhaps a quarter of an inch) a small probe, and that from this exudes a slight thin discharge. Sir James Paget has pointed out that these openings are branchial fistule—are, in fact, 'due to incomplete closure of the upper or first post-oral fissure;

or, rather, of that part of it which is not utilised in the formation of the Eustachian tube, tympanum, and meatus.¹ A very characteristic example of this deformity which I removed from a child in 1875, on account of its unsightly appearance, may be seen in the Museum of the College of Surgeons.

When the malformation of the external ear is great, for the reason above mentioned, the loss of hearing is generally absolute; but it occasionally happens that a child presents some lesser peculiarity, such as closure of the external canal by integument, and is possessed of so much hearing as to enable it to acquire language by the ordinary method, though not until much later in life than usual.

Surgical interference, even when there is considerable hearing, could only be contemplated in those cases in which the deformity seems to be confined to the closure of the canal; but this too often is but a small factor in causes which induce the deafness. It is only, therefore, under very exceptional circumstances that an artificial opening would be serviceable. When it has been made, it has been found very difficult to prevent reclosing of the opening, and the hearing has been but very slightly benefited.

For anyone who has had the opportunity of observing great numbers of congenitally deaf children, it is difficult not to speculate on the possible influences which have aided in their production. Without any sort of doubt, a large proportion of malformations of the external ear, as well as congenital absence of some portion of the tympanum and labyrinth, occur in the children of parents who are blood relatives, and it is scarcely conceivable that these are mere coincidences. Because it is true that a large number of the marriages between cousins are productive of well-developed children, this in no way invalidates the other proposition, viz. that such intermarriages have the aforesaid tendency. My own conviction, as well as that of others who have been brought extensively into contact with the congenitally deaf, is very strong on this point.

In connection with the subject of deformities of the ear may be mentioned the occasional absence of the malar bone, or the zygoma, the substitution of solid bone for the external canal, absence of the tympanum, closure of the fenestra ovalis and rotunda by bone, absence of one or more of the semicircular canals.

Tumours of the auricle.—The so-called hæmatoma of the insane is a roundish red tumour which makes its appearance as an effusion of blood in the course of a few hours, and may be of almost any size up to that of a hen's egg. It is accompanied by heat and pain, and fluctuates. After a time the skin gives way, allowing the blood to escape, or, if not evacuated through an incision, the contents of the blood-cyst after a few months undergo absorption. In either case, but especially in the latter, the subsequent contraction leaves great deformity of the auricle. It is agreed on very high authority that these tumours need not necessarily owe their existence to blows or violence offered to the ears. The best account of them that has been published may be found in Dr. Rossa's work on diseases of the ear, in which the opinions of Virchow, Brown-Séquard, Hinton, and others are quoted. Swellings of a somewhat similar character and appearance occasionally may be met with on the auricle, when they are undoubtedly the result of violence. They are then nothing more than extravasations of blood.

A few instances have been recorded in which the auricle has been the seat of epithelioma. I have seen three cases of nævus in this part, and in all there was a flow of blood from them at the catamenial periods. They were readily destroyed by the electric cautery. Small simple cysts are occasionally found on the auricle, and the piercing of the lobe for earrings not uncommonly gives rise to small encysted swellings, which will not disappear unless they are removed. Calcareous deposits on the auricle in gouty people are familiar to all physicians. Their most usual position is on the upper border of the helix. They occasionally become inflamed, and are then very painful.

Foreign bodies in the ear.—Stones, beads, pieces of wood, berries, cherry-stones,

¹ See *Transactions of the Royal Med. Chir. Society*, vol. lxi.

or any other small objects which fall into their hands, are occasionally put into their own ears, or into those of others, by children at play, and if the occurrence escapes observation, they may remain in the ear for many years without exciting the least irritation or discomfort. When a foreign body has been introduced into the meatus, and has not been interfered with, it will be found in the first portion of the canal, and may be removed with tolerable facility; but, if an unsuccessful attempt has been made to seize it, or if the ear has been syringed in order to expel it, provided that it is small enough to pass the narrow middle part of the meatus, it will at once slip down the second portion, which takes a downward curve to the tympanic membrane. In this position it is by no means so easy of removal.

When light is reflected from the mirror worn on the forehead through a speculum, and the canal is then illuminated, the extraction of a foreign body, if it has not passed beyond the middle part of the meatus, may be effected without any pain or risk of injury to the membrana tympani. If this precaution is taken, but under no other circumstances, the operator may be allowed to select such instrument as the size, form, and general nature of the object may suggest.

In the majority of instances, perhaps the most useful instrument is a simple piece of steel, not thicker than a fine wire, and slightly bent at one end to form a very minute hook; the other end is fixed into a handle. With this little hook the foreign body can be drawn out. If the object present an edge that can be firmly grasped, a long polypus forceps may be used.

Fig. 10.—Forceps for extracting small Polypi.

Adults will sit still in a chair whilst this is being done, as they are not put to the slightest pain; but in the case of children, it is generally better to employ an anæsthetic, in order to ensure absolute stillness.

Should the foreign body, however, have previously been pushed beyond the narrow middle portion of the canal (and this fact is shown by an examination with the reflector and speculum), nothing beyond the most careful syringing ought to be resorted to. A very small nozzle to the syringe should be used and kept close to the upper wall of the canal; the head should be at the time so inclined as to facilitate the rolling out of the object. It is very much to be desired that the order of events in these cases could always be allowed to follow this simple and safe course; but, as a matter of experience, it very frequently is not.

No sooner is a child known or thought to have something in its ear, than the friends at once betray a burning anxiety to have it removed, and either they themselves endeavour to extract it, or some one else is found with sufficient hardihood to make the attempt without the employment of reflected light. The results are then invariably the same. If there is a foreign body, at the first touch it slips through the narrowed portion of the canal on to the membrane. A renewed attempt, accompanied by a movement of the child, ruptures the membrane.

That half, at least, of the patients who are brought to hospitals for the purpose of having foreign bodies removed from the ear are in this condition, and that of these many have had nothing whatever in the ear to partially justify the treatment to which they have been subjected, are matters of common knowledge amongst aural surgeons. It would be well if the ill-directed energy which is so often brought to

bear upon these cases ended with the simple rupture of the membrane; but the struggles of the little patients interfere so much with any further attempt to extract the foreign body (either real or supposed), that it is occasionally thought desirable to place them under chloroform, in order that a renewed groping in the dark may be conducted at leisure. The complete destruction of the membrane and contents of the tympanum is thus achieved. A passing allusion to such proceedings as being by no means of unfrequent occurrence may be pardoned, when it is remembered that the death of children under such circumstances takes place sufficiently often to be recorded in the journals and in recent works upon aural surgery. In the event of a patient in whom the membrane has been ruptured being brought for treatment, the meatus is swollen, and filled with blood, or discharge (if a few days have elapsed since the accident).

It will then be desirable to relieve inflammation with hot fomentations, and when all swelling has subsided, the ear should be syringed every day with warm water. Under such simple treatment, if there is a foreign body in the ear, it will generally come out, or in course of time be moved into such a position that by the means already mentioned it can be easily extracted. The purulent discharge from the ear will continue indefinitely until the membrane heals, which generally happens in course of time, unless it has been completely destroyed; and the extent to which the hearing is lost will depend upon the amount of damage done to the structures behind it.

Occasionally insects crawl into the meatus; syringing will remove them. If the auricular branch of the pneumogastric nerve happens to be situated rather superficially, and a small object remains without being discovered in the meatus, it is apt to excite irritation, and to give rise to a troublesome cough, which is at once relieved when the cause has been removed.

Exostoses.—Enlargements of the osseous portion of the external auditory canal are of frequent occurrence, and they afford on the one hand examples of the symmetry of disease, and on the other of the effects of a local irritation in producing successively increased nutrition and new growths. Thus, in passing under review a large number of these cases which have come under my own observation during several years, it is noticeable that in about half the number of patients who have presented themselves for examination, and to whom bony enlargements were present in one ear, upon inspecting the other ear it was found to be similarly affected, very often not only as to the size, but also as to the number of the growths. A very common form is that in which three enlargements meet in the canal. Sometimes there will be only one, at others two. Attention is generally directed to their existence by the fact of a piece of cerumen entirely closing an already nearly closed canal. Thus they may remain for many years without attracting notice.

In examples of this kind it is quite impossible to state with anything like accuracy the origin of the growths. Many explanations have been offered, such as that they are of gouty or syphilitic origin; but none of these views will bear the test of experience, nor can they be regarded as anything more than conjectural. I have seen several members of the same families the subjects of these bony enlargements, so that they are sometimes inherited. That they will at one time increase synchronously in either ear, that they will remain without apparent change for many years, that if they are uncomplicated with any further affection behind them they are harmless, and that the smallest possible aperture is sufficient for nearly perfect transmission of sonorous vibrations, are so many certain facts. But, if their existence is unaccountable in the one class of cases, their occurrence in the other admits of a tolerably accurate explanation. It often happens that a patient who complains of being deaf in one ear, and in whose external canal one or more bony growths are discovered, will be found to have suffered in early life for many years from a purulent discharge from the ear. The order of events will then have been—inflammation of the middle ear, perforation of the membrane accompanied with the discharge, healing of the perforation, abnormal growth of the osseous canal. Sometimes the perforation is still open, and the discharge may be observed to come from behind

the exostosis. The local irritation produced by the constant passage of this discharge from the open tympanum, especially when the opposite ear is absolutely healthy, appears in such examples to be a reasonable explanation of the origin of the bony growths.

When exostoses have been discovered, the patient should not be allowed at any time to put his head under water, as in bathing. A few drops of water, and especially of sea water, behind the growths are quite enough, not only to make him deaf, but often to excite irritation or inflammation in the neighbourhood or in the substance of the tympanic membrane. Indeed, it is this accident which frequently directs attention to the state of things. For the same reason, when the closure of the canal is completed by a small piece of cerumen, it is better to carefully remove it with forceps, or some appropriate instrument, rather than to syringe the ear. Inasmuch, as in most cases the canal is not absolutely closed, this management is all that is wanted in the way of treatment; but in the example above alluded to, viz. where the membrane is perforated, and in instances where the discharge cannot escape, where there is perhaps a polypus growing from the tympanum, and seen to be protruding between the exostoses, especially when this condition is accompanied with severe headaches and general constitutional disturbance—where, briefly, the patient is in immediate risk of blood-poisoning, or extension of inflammation to the cranium, the removal of the growth is urgently demanded. This is no easy matter, and the writer of this article has arrived at the conclusion, as the result of his experience of such cases, that the best method to employ is as follows:—The patient being under ether, and light being reflected from the mirror worn on the forehead, the bony growths are cut away by the drill which is in common use among dentists. It is, of course, necessary that an assistant should turn the lute, and that the blood which oozes from the bone should be constantly stanchied with absorbent cotton-wool. The bleeding of the bone, by obstructing the view of the parts, makes the proceeding necessarily a tedious one; but the complete command which can be exercised over the drill makes its employment in these cases most valuable. It is, of course, far more easy to remove these growths when they occur singly, as there is then generally a pedicle to cut through; and fortunately, when the enlargements have been the result of a local irritation, it is more usual to find the meatus completely obstructed by one tumour growing from the posterior wall than by two or three. They are of very dense structure like ivory. It is possibly a coincidence, though perhaps worth mentioning, that men are far more prone to this affection than women, and that they very commonly have been in the habit of bathing in the sea a good deal.

Accumulation of cerumen.—Were it not that accumulations of cerumen are very frequently directly and indirectly the cause of much trouble, a few words would be sufficient with which to dismiss the subject. As a matter of fact, however, the presence of cerumen may give rise to very serious consequences. For example, the tympanic membrane is not unfrequently ruptured by violent syringing entrusted to inexperienced hands.

Long-continued pressure from hardened wax occasionally causes ulceration of the membrane, and sometimes even absorption of portions of the osseous canal. Where very dry cerumen has been for some time in contact with the membrane, a few drops of water getting into the ear, by causing swelling of the mass, will so excite pressure as to set up inflammation within the tympanum, as well as throughout the entire external canal. It becomes necessary, therefore, on occasions, to exercise something more than ordinary prudence in the removal of wax from the ear. At other times the canal may be as nearly as possible filled with cerumen without any inconvenience arising from its presence, for the very smallest passage to the membrane will suffice or perfect hearing. When patients become deaf from this cause, they do so suddenly by some slight movement in the mass, occasioned generally by a little water getting into the ear, or by the pressure of the pillow on the tragus. It may be laid down as a rule that an ear should never be syringed unless an inspection has proved the necessity for such a proceeding. A stream of water directed on to the tympanic membrane can

only operate in a harmful manner, and it is by no means a very rare occurrence to find the membrane split vertically on one side or the other of the handle of the malleus, when a person has had the ear syringed by the first person whom he can induce to operate upon him. Even when the presence of wax has been demonstrated, and when it is, as often happens, of stony hardness, it is not always advisable to syringe the ear until the collection has been softened by soaking with warm water; for the first syringe of water will perhaps drive the mass against the membrane, and it may, in its hardened state, be not very easily dislodged at the first sitting. In such a case it is better, even at the expense of a considerable time bestowed on the occasion, that the ear be kept filled with water for some time, and then that the secretion be subsequently removed.

At all times syringing should be employed with the greatest gentleness; the process ought not to cause pain, nor be continued for long at a time. If the above precautions are not attended to, a good deal of irritation may be set up, and the canal become so swollen that for many days it may be quite impossible to remove the cerumen. The most convenient form of ear-syringe is one in which the nozzle is removed (whilst the syringe is filled) and readjusted by a bayonet action. This portion ought to be small in order that it do not block up the canal, and when it is used, should be applied to the roof of the meatus. Its introduction will be much assisted if the auricle is drawn upwards at the time. A feeling of faintness and giddiness is at once produced if the water is not warm enough to be pleasant, and even then there will be found a certain proportion of people whom syringing the ears affects in this way. Indeed, as will be mentioned hereafter, the symptoms of giddiness, and sometimes even of vomiting, without any previous sensation of nausea, are prominent in many cases when either of the three divisions of the ear are disordered; thus showing the very intimate connection which exists between the pneumogastric and the auditory nerves.

Fungi in the meatus.—In 1867 Schwartze directed attention to the fact that the external auditory canal was occasionally the seat of a vegetable fungus, *Aspergillus*, and it has since been found by many others. The fungus is identical with that which is found in the mould on damp walls. When it has been noticed, it has generally been in cases where the canal has suffered from irritation, or collections of cerumen. It is easily eradicated by cleanliness and some local astringent, such as acetate of lead lotion, or spirits of wine.

Collapse of the cartilaginous part of the meatus is an affection of old age. The opening to the canal becomes often in elderly people reduced to a mere slit. When the hearing suffers from this condition, a small silver tube may be worn to keep the walls of the canal apart.

Eczema.—This is a very common affection of the external ear, and often involves the auricle as well as the external meatus. It is generally met with in persons of a gouty tendency, or those who become out of health from too free living and sedentary habits. In the acute form the whole of the external ear is very much swollen, red, and painful, and exudes a watery discharge, which dries rapidly, and becomes encrusted. The itching which accompanies it is most excessive. In this stage the best treatment consists in laxative saline medicine, given very freely; restrictions in diet, such as very little or even no animal food for a few days, and an entire absence of stimulants. The ear should be constantly fomented with hot water; the canal frequently syringed with warm water, and a lotion consisting of oxide of zinc and water may be dabbed on to the ear several times in the course of the day. When under this treatment the acute stage has passed away, an ointment consisting of vaseline and the ammonio-chloride of mercury, eight grains to the ounce, may be lightly pencilled over the ear and within the meatus.

The chronic form of the complaint requires the most patient treatment, and it is very desirable that the affection should not be allowed to go on without attention being paid to it; for not only does it lead to a general thickening and disfigurement of the auricle, but the integuments of the external canal become so much thickened that the passage is at last not infrequently almost occluded. When this disease has

been neglected for some years, I have often seen so much narrowing of the canal that it would only admit of the passage of a small probe. The hearing in such cases suffers very much indeed; for complete closure from the presence of a little dried discharge from time to time takes place. In cases of chronic eczema the first consideration is that the canal should be carefully syringed and dried. At first this ought to be done by the surgeon every few days, and the above-mentioned ointment very sparingly applied with a small camel's-hair brush. A rigid diet, suitable for a gouty person, must be enjoined. Some form of mineral aperient water may be taken in the morning, and a small dose of *Liq. arsenicalis* and bicarbonate of soda twice daily after food. Under simple treatment of this kind patients may completely recover from an otherwise obstinate and interminable disorder.

Boils in the meatus.—The external auditory canal is very often affected by boils, which are so persistent in their advent that it is not very uncommon to find a patient affected in this way, who will for many months not pass a week without a fresh one. No sooner has one boil completed its course than another begins. The first premonitory symptom is generally an intolerable itching. On account of this tendency to recurrence, no local treatment is of any avail until the constitutionally disturbing cause has been discovered and corrected. Strong vigorous men are quite as prone to this very troublesome affection (for the boils are extremely painful) as weakly persons. Men who, after being accustomed to very active exercise, take to sedentary pursuits, are unusually liable to this symptom, and therefore the treatment which was spoken of as being adapted for persons who suffer from eczema is generally in kind the most suitable for these cases. Some simple ointment, such as zinc ointment made with vaseline, will be useful to relieve the itching.

Abscess of the canal requires more vigorous treatment. It is an intensely painful affection, and is very often set up by the irritation of cerumen behind the spot where it forms. It is generally best to open an abscess in the canal, for the integuments are so tense that much prolonged suffering is in this way avoided; and the incision should be made very freely, if it is needed at all. What is generally described as *diffused inflammation of the external auditory canal* occurs more or less whenever the tympanum is also inflamed; it is then confined chiefly to the soft parts of the canal, and the movements of the jaw are very much impeded; but if it is of primary rather than of secondary origin, the periosteum is the tissue affected. In the latter case the canal appears very much swollen, and it is very tender. If the pain, which is extremely severe, does not subside after leeches have been placed in front of the tragus, and followed by fomentations, an incision should be made through the periosteum. This may be conveniently done with a curved bistoury, and the incision should be made as the knife is withdrawn. Unless this relief is given to the extreme tension of the parts, some portion of the osseous canal will afterwards die, and exposed bone in this situation is most troublesome; for it not only is difficult to detach and remove, but from the exposed surface granulations arise which fill the meatus; there is then a profuse purulent discharge from the ear. These granulations become afterwards dignified by the term polypus, and if they are simply removed, will be reproduced very soon afterwards.

In the treatment of this condition, therefore, as in the case of true polypus or any other morbid growth, extraction is merely the preliminary step to treatment. To accomplish their removal the ring polypus forceps may be employed, or any modification of this instrument that the ingenuity of the operator may suggest. Indeed, it is absolutely necessary that several instruments should be at hand, for not only does the meatus of individuals vary very much in calibre, without any reference to the ages of patients; but the size and position of the growths are sufficiently different to suggest the most convenient instrument for their extraction. After the removal of a polypus, or of granulations, some caustic fluid should be applied to the point of origin which is connected with the diseased bone. Chloro-acetic acid is of all others perhaps the most useful, since its action can be immediately stopped, if necessary, by syringing; for this acid is perfectly soluble in water. The best plan of applying the acid is to twist a very small piece of absorbent wool on to

the end of an eye-probe, and moisten it with the caustic. For daily use afterwards, powdered gallic acid may be applied. Of course, complete recovery does not take place until the whole of the dead bone is removed.

THE MIDDLE EAR.

There are certain points in connection with the middle ear which make it as impracticable as undesirable that the subject of diseases to which it is liable should be treated in so divisional a manner that it might be supposed possible to speak exclusively at one time of affections of the membrane, at another of the cavity of the tympanum, or at another of the Eustachian tube. For in practice it is found that the tympanum cannot suffer without the membrane being altered in appearance and structure; that abnormal states of the membrane are for the most part secondary to catarrhal or inflammatory changes within the tympanic cavity; and that any obstruction of the Eustachian tube, from whatever cause arising, not only alters the curvature of the membrane, but also, as a natural consequence, the position of the chain of ossicles which lie across the tympanum. In short, one division cannot suffer without involving, more or less, the other two.

The patient study of the tympanic membrane in disease cannot fail to leave two distinct impressions on the mind of the observer: first, that any alteration in its appearance or structure must be regarded chiefly as an index of changes which have taken place within the tympanic cavity rather than as important in themselves; secondly, that any preconceived notions as to the functions of the tympanic membrane must be often discarded, seeing that such perfect hearing is sometimes present with a membrane as different from health as it is possible to conceive, whilst, on the other hand, extreme degrees of deafness, exclusively dependent on disease of the tympanum, will be found to be associated with nothing more marked than a loss of lustre and translucency in the membrane. It must not be supposed, however, that the most careful study of the membrane in health and disease is likely to prove barren in its results, for the contrary is true. The most trifling alterations in curvature, and the most minute variations from health, especially when these signs are taken in conjunction with the opposite ear of the patient under examination, and the history of the malady, will often form an incident in the chain of evidence which will throw so much light upon the subject under investigation as to make what would otherwise be an obscure case, one readily understood in all its bearings. Thus, a small scar on the membrane will occasionally tell a story of previous inflammation within the tympanum, the details of which had long since passed from the memory of the patient or his friends. It seems almost needless to observe that the appearances presented by a healthy membrane must be, in the first place, perfectly familiar to the student of ear diseases, and perhaps the first thing that he will notice will be the considerable variations which are found to exist in the brightness, translucency, and curvature of the membrane in individuals whose ears are absolutely healthy. No description will fully illustrate this fact, and it is a knowledge only to be attained by a large experience. Speaking generally, however, the chief points to be observed in the membrane are the following:—

(1) The *short process of the malleus*, which forms a projection at the upper and middle part of the membrane.

(2) Proceeding downwards, and slightly backwards, and terminating at a little below the centre of the membrane, the *handle of the malleus*.

(3) Taking the termination of the handle, or umbo (as it is called), for its apex, and extending downwards and slightly forwards, is the *triangular bright spot, or cone of light*. This is an area from which, when the membrane is illuminated, light is reflected back to the eye. It is due to the peculiar curves exhibited by the membrane; curves which are of a somewhat complicated nature, and which are dependent on the conditions that might be expected to obtain when it is remembered that this stretched membrane has an oblique position, forming with the floor of the canal an angle of about 45° , and that it is drawn upon by the handle of the malleus,

which is tilted inwards. Thus, although it is irregularly concave at the centre, its peripheral part is somewhat convex. It will be noticed that this cone of light would be absent if the membrane were a plain surface, and that, as a matter of observation, its position is altered by movements of the handle of the malleus, produced by distending the tympanum with air, and by the removing this distension by the act of swallowing.

(4) *Its colour*, perhaps best described as blue grey, which varies even in health according to its transparency, for under the influence of a very bright light the tympanic cavity is more or less illuminated. The colour is also influenced by the kind of light which is employed, being more blue under sunlight and of a somewhat yellowish hue under the artificial illumination from gas.

(5) *Its lustre*, which is soon lost whenever the tympanum is affected with catarrh or inflammation, as it also is in many affections of the external canal.

(6) *Its inclination*. This varies somewhat; it forms an angle of about 45° with the floor of the meatus.

(7) *Its curvature* presents irregularities, the reasons for which have been previously mentioned, and it also will be found, as will be mentioned later on, to alter in all cases where the middle ear is affected.

For surgical purposes it will be sufficient to remember that the tympanic membrane, consisting, as is well known, of external radiating fibres, derived from the periosteal covering of the external meatus, and internal circular fibres from the periosteum of the tympanum (between these the handle of the malleus is fixed), has, as an external layer, a continuation of the skin of the meatus, and that its internal layer is the extremely delicate mucous membrane which lines the tympanum and the Eustachian tube.

Injuries of the membrana tympani.—The membrane is very frequently ruptured accidentally. This may happen from the introduction of any pointed instrument into the ear; by the violent compression of air within the tympanum, as in vomiting or blowing the nose; by the sudden compression of air within the meatus from a box on the ear, or an explosion near the ear; by a blow or fall on the head; or by a violent syringing. In whatever way the accident occurs, a sudden acute and sickening pain is felt, and this is immediately succeeded by a feeling of faintness. There is perhaps also a little oozing of blood. Even without an examination, the precise nature of the accident may be known by the facility with which the patient can pass the air through the tympanum in a forcible attempt at expiration, whilst the mouth and nose are closed. After the accident, the membrane either heals in the course of a few days, or suppuration is established in the tympanum. There is then a purulent discharge from the ear. But, even if this takes place, the tendency of the membrane is towards healing. When the ear is examined soon after the accident, a clot of blood will sometimes be observed covering the rupture, or the opening may appear like a slit, the edges of which separate if the patient blow through the perforation. Where a sharp pointed object, such as a toothpick, a twig of wood, or the like, pierces the membrane, the wound generally heals very rapidly (in a few days), and very little deafness is ultimately left. Although subsequently the perforation may close; if suppuration has once been established, in some degree, however slightly, the hearing suffers. The function is more extensively injured after rupture, caused by blows on the head or ear, and by explosions, than by any other form of the accident. In truth, however, in these cases, as in all others, the rupture *per se* has very little indeed to do with the loss of hearing, as may be noticed from the fact that shocks of this nature are alike productive of very serious and permanent deafness, whether the membrane be broken or not. In both cases the nervous structures are, without doubt, the parts which mainly suffer. After suppuration in the tympanum, however, a second element comes in, for the products of inflammation within this cavity still further damage the hearing by their interference with the conduction of sound to the labyrinth. Conclusive evidence of the degree in which the nervous portion of the ear is damaged on the one hand, and the conducting portion on the other, is afforded by comparing the manner in which the vibrations of a tuning-fork placed upon the

vertex are heard relatively by the injured and the uninjured ear. Where the nervous power of the ear is damaged, such vibrations will be heard less loudly than in the healthy ear, and more loudly when the conducting power has been impaired in the course of inflammation within the tympanum. It is worthy of notice that far greater damage is done to the hearing by a box on the ear or explosions when they come unexpectedly—i.e. before the tensor tympani muscle has contracted so as in some degree to prepare the membrane for the shock. In accounts of the injuries under consideration, which I have given elsewhere,¹ will be found an instance in which the portio dura was injured in its passage through the aqueduct of Fallopius, by the point of a pair of scissors thrust through the membrane (complete paralysis of the facial muscles instantly followed), and in the twenty-two cases there recorded 'the perforation did not heal in ten; in six instances the hearing did not suffer at all; in the remaining sixteen it was more or less seriously impaired.'

The chief treatment for accidental rupture of the membrane is to prevent the patient putting anything (even water) into the ear, so that the healing process may be allowed to take place without being interfered with. If suppuration takes place, nothing more should be done than gently to syringe the ear with warm water, taking care that occasionally secretion from the tympanum is expelled by causing the patient to blow through the opening. If it does not heal eventually, the case will come within the category of ordinary perforation of the membrane, to be mentioned hereafter, and must be treated accordingly.

The importance of non-interference in these cases cannot be too urgently impressed on the patient, and it is somewhat rare to find instances (unless the patient is seen soon after the accident) in which some sort of an attempt has not been made to assist the healing process which so readily takes place if it is allowed to proceed unmolested. How quickly the membrane heals may be seen at any time if it is examined within a few days of an occasion on which it has been ruptured by a blow or fall on the head which has been followed by some bleeding from the ear. Even in those cases in which the bleeding has been profuse, and in which there has been every reason to believe that the base of the skull has been fractured, the healing process is not very long deferred. The appearance which is presented when the membrane is ruptured from these causes is very generally a longitudinal slit in the anterior or posterior section of the membrane. On one occasion when the accident occurred from the explosion of a gun close to the ear, I observed two slits on either side of the malleus, extending from the top to the bottom of the membrane; they both healed completely within four days of the accident.

In the case of a severe blow or box on the ear, when the hearing is extensively damaged, it generally recovers to a certain extent, and this happens quite irrespectively of any rupture of the membrane. The loss of hearing is always accompanied by more or less tinnitus, and this symptom is the last to disappear, and indeed is sometimes persistent for the remainder of the patient's life. It is very much to be desired that it should be generally known how commonly the practice of boxing boys' ears at school is sometimes followed by most serious and permanent deafness.

NON-PURULENT CATARRH OF THE MIDDLE EAR.

The term catarrh as applied to the middle ear includes in their early stages all the affections to which it is liable, and when it is remembered that the Eustachian tubes and tympana are lined continuously with the same tract of mucous membrane, which is in all cases the part primarily involved, the application of this term is a very natural one. So long as the increased secretion is merely of a mucous character, the disease is spoken of as non-purulent, but if the process of congestion passes into that of inflammation, and the formation of pus takes place, the term purulent catarrh is applied to the affection. This division is not so artificial as would appear at first sight, for although the one may be sometimes merely the first stage of the other, it is found in

¹ Vide *Transactions of Clinical Society*, vol. vi., and *Lancet*, 1875.

practice that the middle ear may for years be affected with increased secretion of its lining membrane, without ever suffering from inflammation in the true sense of the word.

Obstruction of the Eustachian tube.—In the simplest form of catarrh, nothing more than the faucial openings of the Eustachian tubes are involved, and the symptom complained of is deafness, accompanied by a sensation of weight in the ears. It is a very common ailment with children and young persons, and whilst the so-called strumous are more liable to it than others, it is by no means confined to this class. More often than not it is associated with a granular condition of the pharynx and posterior nares. For this reason the subjects of it present a very characteristic appearance, since they breathe almost exclusively through the mouth and more habitually during sleep. The temperate damp climate which prevails in this country and Germany is peculiarly favourable to its development. In children with this complaint the hearing varies very much according to atmospheric influences and the especial locality in which they reside. Thus a clay soil is especially unfavourable to these patients; also they hear much better in summer than in winter; and if they remove into a dry warm climate, recovery occasionally takes place without further interference. Under ordinary circumstances it is of primary importance that the condition of the nares should be attended to, and this may be done by the daily syringing of the nostrils with alkaline or saline solutions. Salt and water, sea water when obtainable, or a solution containing carbonate of soda, borax, and sugar, are amongst the most suitable. The fluid should be warm, and must be syringed in such a manner that it passes chiefly through one inferior meatus of the nostril and out through the other; and whatever of it passes into the throat must be spat out. In this way large masses of secretion will be brought away, and after a time free breathing through the nose is established. This plan is much to be preferred to the nasal douche, the use of which is without doubt not free from danger. When it is employed, it occasionally happens that some of the fluid passes through the Eustachian tube into one or other tympanum, and sets up inflammation, which ends in rupture of the membrane, accompanied by more or less disorganisation.

The subjects of this catarrhal malady, especially when they are of a strumous type, often have enlarged tonsils. Although the tonsils do not mechanically in any degree close the Eustachian tubes, they keep up the unhealthy condition of the pharynx, and interfere with the respiration. They should then be removed. When it is added that Politzer's method of inflation ought to be occasionally practised, the routine of treatment has been indicated. This simple and useful proceeding is a very important element in the successful management of a case, not only because it instantly improves the hearing, but because it relieves the extreme tension to which the membrane is subjected when the tympanum is not constantly replenished with air. It may with benefit be repeated at intervals; but, inasmuch as its employment is extremely grateful to the patient, it is necessary to guard against its abuse. It is unfortunately sometimes practised with too great violence, and has often within the writer's experience caused sudden rupture of the membrane. Its too frequent use also tends, by stretching the membrane, to cause its permanent relaxation.

From whatever cause the Eustachian tube is obstructed, the membrane presents in a degree the same appearances. They are such as might be expected when air in the tympanum, not being regularly replenished, undergoes partial absorption. For whilst the density within the middle ear is in this way diminished, that of the outer air remaining the same, pressure is produced on the membrane, and on the chain of ossicles which rotate with its movements. In an extreme case the short process of the malleus will seem to be bursting through the membrane; the handle is tilted backwards till it is almost in contact with the promontory, and the central concavity of the membrane is much increased.

From the short process proceeding horizontally backwards in the posterior section of the membrane may be seen a ridge or fold evidently produced by the altered position of the malleus, since it disappears after inflation of the ear has been practised. The condition of the posterior nares already referred to is very often the result of scarlet fever or measles. Obstruction of the Eustachian tube may take place

in adults, even in good health, and apparently without any predisposing cause beyond an ordinary cold, and it is quite in accordance with experience to find one tube affected as often as both. If attention is directed to the matter before it has been of long duration, a few inflations and the use of some simple saline syringed through the nares, will suffice to remove the obstruction; but, unless some relief of this kind is afforded within a reasonable time, the use of Politzer's method will not succeed in opening the tube, and it then becomes necessary to make use of the Eustachian catheter. This instrument (the employment of which is mainly useful for injecting fluid into the tympanum in cases of catarrhal affection of this cavity) may be made of silver or vulcanite. The latter kind can be bent to any curve required by slightly warming, and then allowing them to cool whilst the necessary curve is maintained by the hand.

Three or four different sizes are enough for ordinary use. The purpose served by the metal ring is to show the position of the instrument in passing it—that is, whether the point is directed to the left, the right, downwards or upwards. The other end receives the india-rubber bag which is employed in injecting air or fluid into the middle ear. The mode of passing the catheter is as follows:—‘Place the patient in a chair, and let him lean back in it; steady his head with the left hand, firmly fixed on the top of it; hold the catheter lightly in the right hand, with the curve downwards, and pass it quickly in this position through the inferior meatus of the nose to the posterior wall of the pharynx. When this is felt, withdraw the

FIG. 11.—A. Vulcanite Eustachian Catheter. B. Silver Eustachian Catheter.

catheter about half an inch, and tilt the point of the curved end rather upwards and to the left or right, according to the side which is being operated upon. Now hold the catheter and end of the patient's nose steadily between the thumb and the first two fingers of the left hand. All this time the ear of the patient and surgeon are connected by the diagnostic tube. The point of the catheter is now supposed to be in the pharyngeal opening of the Eustachian tube; but the only certain sign of this being the case is that, when air is forced into the catheter, it will be heard through the diagnostic tube to impinge upon the tympanic membrane when the stream of air is passed down the catheter (I am presuming that the Eustachian tube is not occluded). This is the most common method of using the catheter, and I think it is the best.'

After some little practice the mistakes which are made by those not in the habit of using this instrument will be avoided. They consist chiefly in not keeping the point of the catheter in contact with the inferior meatus, and so passing it into the middle meatus, and in not withdrawing it far enough before turning it outwards. The proceeding, although unpleasant to patients, is not painful, and they for the most part soon become so tolerant of it, if it is passed rapidly, as not to object to its use. With others the nostril is so sensitive as to make it always most unpleasant. The real difficulties which are met with consist in the facts that the septum of the nose in some persons is not placed vertically, but inclines to one or the other side, generally to the left, and that the inferior turbinated bone is occasionally much larger than usual. The meatus is then quite impassable for even the smallest instrument. In these cases it is sometimes possible, by greatly increasing the curve of the catheter, to introduce it through the opposite nostril. Patients who require the employment

¹ Vide *Lectures on Diseases of the Ear*. Dalby.

of the Eustachian catheter frequently, should be provided with one for their exclusive use, and this, for obvious reasons, should be the invariable rule if they are the subjects of constitutional syphilis.

When Politzer's inflation has failed to open the Eustachian tube, the catheter will generally succeed. It is necessary to repeat the operation at intervals until the middle ear becomes habitually filled with air without artificial means. The complete inflation will be often aided by placing a drop or two of warm water in the open end of the catheter after it is in position and before the bag is compressed. It is probable that the manner in which this acts is by dislodging some small particle of mucus. In some cases of extreme obstinacy in which the Eustachian tube has been obstructed for many years, the introduction of a small laminaria bougie through the catheter will sometimes effectually relieve an otherwise intractable condition. It is necessary to bear in mind that where this method is employed the bougie must be measured, and the distance thought desirable to pass is marked before it is inserted into the catheter, or it might unwittingly be passed into the tympanum; the extent of one inch (the length of the cartilaginous portion of the tube) will be sufficient, or at the most one inch and a quarter. After it has remained in situ for a few minutes, the catheter and bougie ought to be withdrawn simultaneously, as, unless this is done, the latter might break off and be left in the tube. This accident is mentioned by the late Mr. Hinton as having occurred twice in his practice, and although no evil consequences ensued, the fragment coming away on the next day, it is clearly important that the risk of this occurring should be avoided. The cases in which this somewhat severe treatment is necessary are not very numerous, and require a rather careful selection; for when the tube is so effectually closed to the entrance of air, this condition is often associated with old adhesions in the tympanum, the remains of inflammation which has taken place in previous years; the admission of air to the tympanum will not then effect the relief which, in the absence of tympanic disease, might ensue. The history of the case and the appearances of the membrane will, however, decide this question.

Affections of the tympanum.—The tympanum may become the seat of catarrh, by extension from the Eustachian tube, or the lining membrane of the cavity may be primarily affected. In either case the results are the same, both in kind and in the effects which they produce on the hearing by interfering with the conduction of sound. In the early stages of this disorder the swelling of the lining membrane effectually prevents the entrance of air into the tympanum. Increased secretion more or less fills it with mucus, and, in addition to the aforementioned signs of obstruction which the membrane exhibits, its translucency is lost. The presence of secretion within the tympanum may be recognised by the sounds that are heard through the diagnostic tube when air is forced into the middle ear with a Politzer bag; and that the deafness is dependent on faulty conduction can be at once shown by a simple experiment with the tuning-fork. If, whilst in a state of vibration, this is placed on the vertex, the sound will be heard exclusively by the affected ear. This arises from the fact that vibrations through the cranial bones make their impressions on the labyrinth without the aid of the tympanum, and that, in their passage outwards through this cavity, they become again reflected by the obstruction on to the nervous structures.

In this hypothetical case the opposite ear is presumed to be healthy. Whilst on this subject, it may be as well to observe that the value of experiments with the tuning-fork as an aid to diagnosis depend on the following facts.

(1) Let a vibrating tuning-fork be placed upon the vertex of a person with good hearing, and it will be found that he hears the sound quite equally with both ears; that when he can hear it no longer, if it be held near to the meatus, the sound is still plainly audible, thus showing the value of the tympanum as a conducting apparatus.

(2) If, whilst a vibrating tuning-fork is on the vertex, one meatus be closed, the sound will be heard most intensely or entirely in this ear. The same result will

follow if there is cerumen in the canal, or, as was explained, if there is mucus in the tympanum, or, in short, if there is any obstruction to the passage of sound through the conducting media.

(3) A person in whom the nervous function of both ears is defective will hear the tuning-fork on the vertex indifferently, or not at all, and, if one ear only is thus affected, he will hear it exclusively in the normal ear. In estimating the advantages of this test, it is well to remember that occasionally persons with apparently good hearing do not readily hear a tuning-fork placed on the vertex; but such instances are so exceptional that they scarcely need be taken into account.

In a recent and slight attack of tympanic catarrh, the main object of treatment is to keep the cavity occasionally replenished with air, until all catarrhal symptoms have subsided. If this is carefully done, a complete recovery may be expected; but in actual practice the patient seldom consults the surgeon at so early a period, and it is frequently not until some months have been allowed to elapse, or after several attacks, that the case comes under observation. In the course of one or more of these there will probably have been considerable, or even intense, pain in the ear. Whenever this occurs, the results are more or less serious on the hearing; and it may be accepted as a rule in treatment that, if the tympanum can be said to be inflamed (and it always is when there is pain), leeches should be applied in front of the tragus, and fomentations be afterwards continued until the pain is gone. The importance of attention in this direction can hardly be over-rated; for, without any sort of doubt, catarrhal inflammation of the tympanum is, in the results which it leaves, an infinitely more frequent cause of impaired hearing than any other disease of the ear.

These results include occlusion or obstruction of the tympanic opening and the Eustachian tube; thickening of the lining membrane of the tympanum, collections of moist or dry mucus which form around the ossicles, adhesions between the ossicles themselves or between these and the tympanic wall, adhesions connecting the membrane with the several parts of the tympanum, anchylosis of the ossicles, changes in the tympanic membrane such as chalky deposits, relaxation and collapse of the membrane, thinning in parts of its substance, and, when suppuration has taken place, perforation or entire loss of the membrane, and, lastly, caries of the bone.

Opacities of the membrane, whether in the whole or part of its area, are significant only of the fact that at some time or other the tympanum has suffered from catarrh; and since it is quite possible that at the time of the examination the tympanic cavities may have entirely recovered, the appearance is observable in persons of good hearing power as well as in those with whom it is deficient.

Extensive *calcareous deposits* (which consist of phosphate of lime) are also very frequently met with in the membranes of persons with normal hearing. When, therefore, this form of degeneration is accompanied with failure in the conduction of sound, the impairment of hearing must be regarded as depending upon disease of the tympanum, and not, as might from a superficial examination be supposed, upon the alteration in structure of the membrane itself. The constant occurrence of calcareous degeneration, when it is found to be associated alike with normal hearing, with absolute deafness, and with all intermediate stages, very completely disposes of the notion which was formerly held, that 'thickening of the membrane' is a common cause of deafness; and when it is a matter of knowledge amongst those who see large numbers of cases that nearly perfect hearing may exist when the membrane has been almost entirely lost by ulceration, it is time that the views which are popularly held as to the functions of this structure should undergo some modification. If to these facts are added the record of cases in which the membrane has been accidentally ruptured without any appreciable loss of hearing power, and of others where pressure on the malleus is capable of changing most defective to excellent hearing, it is not giving too much credit to pathology to say that the functions of the tympanic membrane are better understood than they were, owing to the study of its diseases. It might be permitted to the present writer to express the opinion that, whilst the province of the membrana tympani as a medium of the conduction of sound must be regarded as very slight, its uses as a protection to the tympanic

cavity, and as a ligamentous support to the chain of ossicles, ought to be considered as its principal functions. Although these calcareous deposits can (as has been said) be seen in otherwise healthy ears possessed of good hearing power, they are more commonly present after the tympanum has been at some previous period acutely inflamed; so that, if in the former case no precise explanation of the existence can be given, they are in the latter, without doubt, a form of degeneration depending on inflammation.

Relaxation and collapse of the membrane are amongst the results of long-continued catarrh. There is no question but the presence of mucus within the tympanum, by long-continued pressure, will cause thinning in places of the substance of the membrane, and thus bring about a condition of relaxation; but the extreme examples of this state are generally induced in the following manner. When a patient with chronic obstruction of the Eustachian tube discovers or is told that he can increase his hearing by forcing air into the tympanum, he acquires the habit of doing this whilst he closes his nostrils with his hand. Patients will get so entirely into this habit that they will practise it more or less all day whilst they are conversing or listening to anything. The result is that the membrane becomes stretched to such a degree that with each inflation it bulges outwards, and in a few moments can be observed (if it is submitted to inspection at the time) to drop backwards again. Sometimes the membrane, under the constant repetition of this practice, becomes so thinned as to exhibit upon inflation bladder-like protrusions. This very characteristic appearance is not uncommonly brought about by the injudicious use of a Politzer Bag. I have myself constantly seen it in the case of young people whose friends, fancying that they have discovered a method by which they can cure the child, have made a daily practice of using the air douche, and in doing so have applied far greater force than is necessary or prudent. On some occasions when the membrane in this state is being subjected to pressure, the thinned portion gives way, and soon after the admission of the external air a purulent discharge is established and escapes through the perforation. Even in the less extreme cases, the air douche should be at once discontinued, and a small disc of moistened cotton-wool be adjusted on to the membrane and worn for a part of a day; its effects are sometimes most beneficial in restoring the membrane to a more healthy tone, and giving the support which had been lost to the malleus. In the relaxed and thinned state of the membrane, acquired either in the above-mentioned manner or by the prolonged pressure of mucus upon its internal surface (as might be supposed when the middle ear is not distended with air), it falls back on the posterior wall of the tympanum, and becomes more or less completely collapsed; adhesions form between it and the promontory, and the incus, and sometimes the stapes, can be distinguished behind it.

Accumulations of serous fluid and mucus often remain for considerable periods in a more or less fluid state within the tympanum. For these cases it is occasionally of the utmost benefit to the hearing if a vertical incision be made with a cataract needle behind the malleus, and the mucus be expelled through the cut by the patient blowing through it, or by the use of the air douche. The late Mr. Hinton was in the habit of syringing from the meatus through the tympanum and Eustachian tube by means of a syringe, the nozzle of which was made to fit tightly in the external canal. This proceeding, however, sometimes sets up irritation in the tympanum. The plan is certainly not so much in favour at the present time. After the expulsion of the secretion, the cut heals in the course of two or three days. The indications for the employment of this operation are the squeaking, bubbling sound which may be heard through the diagnostic tube whilst inflation is practised, as well as the bulging and discoloration of the membrane produced by the secretion. Patients with this affection will often hear much better whilst lying down. This is owing to an alteration in the position of the mucus, as, on resuming the erect position, the deafness at once returns.

When what may be called the dry state of the tympanum has been reached in cases of old-standing catarrh—that is, when the fluid portions of any increased

secretion have undergone absorption, when the inflation of the middle ear gives no improvement; when, in short, the failure in the conduction of sound is due to a thickened state of the lining membrane of the tympanum, and the other changes within it that have been spoken of as the results of catarrhal inflammation, the treatment which has the most beneficial effect upon the hearing is the injection of fluids into the tympanum through the Eustachian catheter. When the catheter has been passed in the usual manner, it is steadied with the left hand; about thirty minims of the solution are passed into the open end by a glass syringe or a pipette, and if the india-rubber bag, elsewhere spoken of, is now applied and compressed, some of the fluid may be heard through the diagnostic tube to pass into the tympanum. The fluid does not all pass into the tympanum, since it leaves the catheter in the form of spray; so that there is no danger if this plan is adopted of the fluid being in such quantity as to sink down into the floor of the tympanum and excite irritation. The cavity becomes bathed rather than filled with the fluid. The solutions which are found to be most useful are those composed of bicarbonate of soda or iodide of potassium, about five grains to the ounce of warm water, or simply warm water. The injection should be practised for a time daily, or two or three times in the week, and the air douche should be used occasionally. That a very considerable proportion of cases improve under this treatment experience amply proves; but it is not very easy to say in what way these injections precisely act. Possibly the dried mucus becomes softened under their influence, old adhesions give way, and a beneficial influence is exerted upon the lining membrane of the cavity. After this treatment has been pursued for some time, improvements in hearing sometimes suddenly occur, so that it is fair to conjecture, under such circumstances, that adhesions do give way, or that some movements take place in the morbid secretion which has become softened. This method of treatment seems especially suited to a class of cases which have been described by Dr. J. Gruber, under the title of Proliferous Inflammation of the Tympanum, and this term has since been adopted by many writers upon ear disease. The patients who suffer from it can give no precise history of catarrh of the pharynx or nares; the symptoms of deafness and tinnitus are gradual and progressive; the Eustachian tubes are pervious, and air enters the tympanum with a dry sound. A most detailed account of the pathology of this affection may be found at page 514, 'Ohrenheilkunde,' Wien, 1872. Sufficient to say that the changes therein described include in succession hyperæmia of the lining membrane, increase of connective-tissue corpuscles, hypertrophy, and granular formations which undergo molecular disintegration, become fatty, and are absorbed or become chalky.

It is right to mention that the practice of injecting fluids into the tympanic cavity has been abandoned by many surgeons of high repute, and the causes for this abandonment have been stated by them to rest upon two very sufficient reasons—viz. first, that the results have not proved satisfactory, and, secondly, that the cause of the failure in treatment is probably due to the fact that inspissated mucus or other products of inflammation are absolutely insoluble in any of the fluids which can or have from time to time been made use of. The fact of this insolubility is undoubtedly true, and it can only be urged in favour of the practice that, in a certain number of cases, patients undoubtedly receive benefit, and that in such instances this benefit probably is not due to the solvent powers of the injected fluid, but rather to their action upon the tympanic cavity, to which reference has just been made.

It is also not very easy to explain the precise manner in which the fumes of muriate of ammonia act upon the lining membrane of the middle ear; but it is certainly true that such treatment of chronic catarrh of this tract of mucous membrane is often in the highest degree useful; and patients who have been taught how to apply the remedy will continue it for long periods, at intervals, of their own accord, because they derive considerable relief from its employment. The fumes of muriate of ammonia may be readily applied to the tympanum by means of a most simple inhaler made for the purpose. The fumes of ammonia, acting upon strong hydrochloric acid, are drawn through water by means of a piece of glass tubing, as in smoking a

pipe, whilst the mouth is filled with the fumes; by attempting to forcibly expire (the mouth and nose being closed at the time) the whole of the middle ear is acted upon by the muriate of ammonia.

A brief reference has already been made to the much-debated question of operations which involve an incision in the tympanic membrane, and I have contented myself with saying that, where there is distinct evidence of serous or mucous accumulation within the tympanum, if a vertical incision is made in the posterior section of the membrane, and the secretion is evacuated by blowing through the cut, very great benefit to the hearing constantly follows.

An account of disease of the ear could not be considered to be otherwise than incomplete if mention were not made of operative proceedings on the membrane, which have been recommended and practised by continental surgeons.

In approaching this matter, it may be observed that the literature of the subject is voluminous in the extreme. Still the most scanty history of all the operations which have been devised and practised would be out of place in this article unless results could be brought forward such as would justify the performance of similar operations in ordinary practice. The class of cases for which they have by their respective advocates been suggested are the so-termed proliferous catarrhal affections of the tympanum, and the object in view has been twofold: either to make a permanent opening in the membrana tympani, or by an incision in this structure to relieve undue tension. The nearest approach to the first result was attained by Dr. Adam Politzer, who, after making an incision in the membrane, inserted an eyelet into the opening. This may be readily done by the forceps made for the purpose; but it is found that, after a few weeks, or months at the most, the eyelet either drops into the tympanic cavity or the meatus, and the opening eventually heals. Some years ago, in common with many others, I made use of this method, but without any permanently satisfactory benefit. Voltolini's paracentesis by the galvano cautery, Gruber's flap in the membrana tympani, Lucass's and Politzer's incision of the posterior fold of the membrane, Prout's division of adhesions between the membrane and promontory, besides other proceedings of a similar kind which have been dignified by the term operations, when stripped of their pretentious nomenclature, are neither more nor less than incisions into the membrane, which heal in the course of a few days. In 1868, Dr. T. A. Weber, of Berlin, first divided the tendon of the tensor tympani muscle, and in 1872, and subsequently, he published accounts of the results of this operation.

FIG. 12.—Knife for making incision in the Tympanic Membrane.
(Handle in figure half the length.)

I think it but right here to say that it is not without a very large personal experience of operations on the tympanic membrane in the cases under notice that I venture to express my opinion on the position which they should hold as remedial measures, and I should still hesitate to do this if I were not fully aware that it is an opinion which is shared by the leading aural surgeons in America (in which country otology has been most extensively and successfully practised), and, with few exceptions, by those in Europe.

Up to the present time the results of all the various operations have not been equal to the expectations which were formed of them. So far as concerns those which have had for their object a permanent opening in the membrane, they have signally failed, and this has been due to the great tendency to repair which the membrane possesses.¹ Where incisions have been made, and allowed to heal without

¹ An account of an operation by M. Paquet, of Lille, may be seen in the Transactions of the International Medical Congress of 1881 held in London. He divides the tensor tympani muscle, and attempts a permanent opening in the membrane, with perhaps better success than has hitherto been attained.

any interference, considerable benefit has followed in a certain proportion of the cases operated upon, in others none at all. As to the division of the tendon of the tympani muscle, it cannot be doubted that it would by this time have become an established operation if its results had proved sufficiently satisfactory. It would be too much to say that this is the case. Ample opportunities have been given to surgeons of seeing patients upon whom this has been practised, and the operation has been performed by others besides its originator.

We have, at any rate, become familiar with the fact that an incision may be made into the membrana tympani without danger to life, or injury to the hearing, so long as before the operation the nervous structures of the ear are unaffected, and it is earnestly to be hoped that some surgical procedure may in time be found which shall have more brilliant results than those which have hitherto been attempted.

If I were to express my own view of the causes which may be said to have improved the hearing where this change has happened, I should say that tension has been relieved, and that adhesions between the membrane and the tympanic wall have been divided—adhesions the existence of which it has been impossible at the time to do more than conjecture. It will readily be understood, therefore, how difficult it must be to lay down any rules by whose guidance the surgeon may select cases in which he may deem it advisable to make an incision into the membrane.

To say more than this might be misleading, and nothing less than a considerable experience in successes and failures will be likely to lead to good averages in a number of cases treated by any operation which includes incision of the tympanic membrane. One of the best opportunities of comparing the opinions of the leading otologists of Europe and America on the subject occurred at the International Medical Congress in London in 1881. On that occasion the principal countries of Europe and the United States were most fully represented, and there could be no question but that the general opinion was of no more definite a character than the one which I have here ventured to express, when the question as to the 'Value of Operations, in which the Tympanic Membrane is incised' was discussed: and let it be here said that this question was discussed in the most exhaustive manner.

INFLAMMATION OF THE TYMPANUM.

The cavity of the tympanum very commonly is the seat of inflammation during some one of the exanthematous fevers, especially in scarlet fever and measles, by extension of inflammation from the fauces. An ordinary catarrh of the middle ear may merge into inflammation, or the tympanum may become acutely inflamed quite irrespectively of the Eustachian tube. At all times, in consideration of its occasionally terrible results, this affection must be regarded as a most serious one. In the case of the fevers, it is so rapid in its progress, and the importance of the general state of the patient so engrosses the attention, that it generally escapes observation until the membrane has given way, when a purulent discharge points to the ear complication. In a person of ordinary health, the first symptom is acute pain, which soon becomes of a throbbing and agonising character, deeply seated in the ear, and sometimes extending over the side of the head. The membrane is, on inspection, seen to be of a bright red colour, and after a few hours appears to be much collapsed and sodden. The act of swallowing is painful, and if inadvertently air is blown into the ear whilst the patient uses his handkerchief, the pain is intense. There is considerable deafness and tinnitus. The temperature is heightened, and there are general feverish symptoms. If at this period leeches are applied in front of the tragus, and hot fomentations freely used, the acute symptoms may subside without the membrane giving way, and more or less complete recovery take place afterwards under the treatment for ordinary catarrh of the middle ear. Should there be a distinct appearance of bulging in the membrane, an incision in this spot for the evacuation of pus ought to be made at once. It more commonly happens

that the membrane has become perforated before the patient is seen, and there is a discharge. Then the main object of treatment is to induce healing of the open tympanum. The ear should be syringed frequently during the day with nothing more than warm water. All astringent solutions ought to be sedulously avoided. They are extremely painful to the recently exposed surface of the tympanum; they retard, and often altogether prevent, closure of the rupture, by inducing cicatrisation of the edge of the perforation, and they increase very much the symptom of deafness. As the purulent discharge becomes less in quantity, and more thin in character, it is desirable that the patient should blow gently through the perforation whilst the ear is being syringed. Accumulation of secretion in the tympanum is thus avoided, and it is the presence of such collections which retards the healing process. Under this extremely simple management many quite recent perforations heal. The tympanic membrane, supplied so plentifully as it is with blood-vessels, has a great tendency to heal, and this is abundantly shown in the cases of infants and young children. What is more common with little children than severe pain in the ear, followed after some hours of evidently acute suffering by a discharge from the ear—discharge which, after lasting for some days or weeks, gradually ceases! I have in common with others found, times out of number, the discharge to be dependent on a perforation of the membrane; and, upon examining the ear some months afterwards, seen the membrane perfectly entire. I may here be allowed to say that I feel confident that the convulsions of children are often due to brain irritation from an inflamed tympanum.

But, if a perforation does not heal within a short period of its establishment, it may remain indefinitely as a fistulous opening, and frequently does, during an entire lifetime. The sizes and shapes of perforations are various in the extreme. Sometimes the loss of substance is so small as only to represent a small opening, such as might be made by a pin, whilst at others the entire membrane is lost by ulceration, the malleus being left in its natural position, or the head of the bone only remaining. Between these, an almost endless variety.

Still, the forms which perforation assume exhibit a certain uniformity. Thus, a very common appearance is that in which the perforation involves the lower half of the membrane, and is kidney-shaped, the hilus of the kidney being represented by the extremity of the handle of the malleus. Sometimes one-half of the membrane is deficient, the handle of the malleus forming the median border of the opening. Or circular portions of the membrane are seen in either the anterior or posterior section, which have the appearance of being punched out. Especial attention should be always directed in examination of the membrane to the folds of membrane which lie in front and behind the head of the malleus, at the upper border of membrane—minute perforations in these positions are liable to escape observation. They are very unmanageable, since purulent secretion within the tympanum escapes through them with great difficulty, and I have often found that they are associated with diseased bone. The edges of an old perforation very generally present an unhealthy granular appearance, and granulations are likely to extend over the external surface of the membrane. In this case on a first examination one may readily fancy that much more of the membrane is deficient than really is so, and if parts of the membrane thus covered are connected to the posterior wall of the tympanum, the aspect is still more delusive in this respect.

The loss of hearing in perforations of long standing bears no kind of relation to the amount of tissue which has been destroyed in the ulcerative process. Intense deafness with a minute perforation, and fairly good hearing when little of the membrane remains, are as commonly met with. As previously intimated, extensive observation in this, as in all other states of the membrane, conclusively proves that the symptom of deafness depends upon disorganisation within the tympanum, excepting so far as loss of the membrane has interfered with the function which it fulfils of being a ligamentous support to the chain of ossicles. In the treatment of old perforations the same careful attention should be given to cleanliness as in recent ones, and the use of strong metallic astringents be guarded against. Their

employment may certainly have the effect of lessening the discharge, and so raise delusive hopes as to permanent benefit; but no sooner are they given up than the discharge is as copious as before. They increase the symptoms of deafness, occasionally give great pain, and that they exercise no permanently beneficial influence on the exposed mucous membrane of the tympanum is shown by the fact that persons of large experience in the treatment of ear disease are scarcely ever found to recommend them. Amongst local applications, perhaps the most useful is a weak solution of alcohol. About one drachm of rectified spirit to three ounces of water is strong enough to commence with, and the proportion of spirit can be gradually increased so long as it does not cause pain.

This application seems to be especially suitable to children. If the membrane is largely perforated and covered with granulations, under the use of gallic acid in powder the condition of the ear is often much improved. But the treatment which supersedes all others in value is the application of some form of covering to protect the tympanic cavity from the action of the external air. To carry out this successfully, the patient must be taught to construct and apply with forceps a piece of moistened cotton-wool of the size and form which is found by experiment to be most comfortable, to afford the most complete protection, and to give the best results in hearing. Improvement in the latter direction is often very extensive, and the principle which is involved is the same as in all the forms of artificial membrane (so called) that have been suggested and used since the time of M. Toynbee. It consists in the fact that pressure is exerted upon the malleus, and so on through the incus, to the stapes. Thus the natural support to the chain of ossicles, which has been lost when the membrane has suffered from ulceration, is in a measure restored. The ingenuity in this application acquired by patients is very remarkable, and they are able to discover, after some practice, the precise amount of pressure required. The local effect upon the ear which follows the exclusion of air from the tympanum is not the least important part of the proceeding. Under this influence the discharge very generally becomes reduced to a minimum, and granulations, if present, disappear. Of course this plan of treatment is not applicable to children or very young persons, who can neither acquire the necessary skill nor will exercise the requisite care and perseverance. The artificial membrane (of Toynbee) is rather irritating, and the india-rubber disc is very liable to break off the wire and become fixed in the tympanic cavity. I have on a great many occasions been requested to remove it after this accident. In the case of perforations which have existed for many years, if under favourable circumstances, the ear becomes more healthy, large portions

FIG. 13.—Forceps for adjusting Cotton-wool.

of the membrane are restored, even to the extent of one-half or more. It is impossible to predict this event in any case, and the fact that this does take place becomes known only when opportunities, which are occasionally met with, of seeing patients with an entire membrane, who, by reference to a case book, were known to have a perforation some years previously. When the healing process once sets in, to judge by what takes place in cases of recent perforation, it is completed in the course of a few days. Scars on the membrane are sometimes represented by calcareous deposit, or, where large portions of tissue have been restored, the position of the perforation is seen to be occupied by what is evidently a much thinner part of the membrane than the rest.

Facial Paralysis.—When inflammation of the tympanum has been so extensive as to result in necrosis of that part of it in which the portio dura is imbedded, the nerve occasionally becomes destroyed, and permanent facial palsy takes place. But a moderately severe pain within the ear, lasting perhaps for only a few hours, not followed by rupture of the membrane, and leaving only a slight and temporary

deafness, is not unfrequently succeeded, by complete facial paralysis, and a period of many months elapses before the muscles regain their original power. That this serious lesion should follow on so apparently a trivial cause appears to be due to the fact that the bony protection to the nerve in its passage through the aqueduct of Fallopius varies very much indeed as regards its thickness in different individuals, and it is in those cases where it is exceptionally thin or perforated by minute holes, as it sometimes is, that a slight degree of inflammation is sufficient to arrest the functions of the nerve. The old-fashioned plan of blistering the mastoid process, if ineffective in other affections of the ear, appears to have a decidedly beneficial influence on these cases. The blisters should be applied at short intervals for several months. The application of electricity to those cases in which the nerve has the capacity, so to speak, of recovery has proved of very great service.

Polypus of the ear.—The appearance presented by a polypus which protrudes from the meatus is that of a fleshy tumour. It bleeds when it is touched, and is attended with a purulent discharge. The seat of origin is sometimes the meatus, usually the posterior wall. It is then very often connected with diseased bone, and after its removal the tympanic membrane may be found to be healthy. Most frequently polypi have their origin in the lining membrane of the tympanum, and are brought into existence by the continuous discharge from a perforation. In the ordinary form they are in structure fibro-cellular, the fibrous element predominating in proportion to the age of the growth, and in their microscopical characters exhibit an appearance very like fibrous tissues in the course of development. Some growths which I have removed have been found to present the characters of myxoma, containing in parts elastic fibres, and in the case of a tumour which had recurred on thirteen occasions after removal, it proved to be a round celled sarcoma. A polypus may not only fill the canal and protrude from the ear, but may cause absorption more or less of the bony part of the canal meatus. The membrana tympani has very generally been lost by ulceration before the beginning of the new growth, but a small polypus may sometimes be noticed protruding through a perforation of even moderate size, showing, without further demonstration, from whence it must spring. Occasionally, though very rarely, polypus grows from the edge of the perforation. The treatment of a polypus consists in its removal, complete eradication, and in the management of the perforation, such as has been already described. Unless the two latter portions of the treatment are very rigorously carried out, it is absolutely useless to take away a polypoid growth. No sooner is it removed, than it at once begins to grow again, so that, unless the patient is prepared to give some time and trouble to the after treatment, the surgeon will do well in not undertaking the case. The ring polypus forceps, of which a number of sizes should be within reach (on account of the variation in the size of the meatus, and the position and form of the growth) is the best instrument to employ in extraction of a polypus; but, as a matter of fact, the instrument which is used is of secondary importance. The appearance of the growth, a careful examination with a probe, the facility with which the pedicle (if there is one) can be grasped, will suggest the most convenient instrument: so that a Wilde's snare, or any of the many forceps which have been devised, may be employed according to the fancy of the operator. In practice the tumour is often found to be so friable that it is necessary to take it away bit by bit. This is not of any importance so that it is completely taken away, and occasionally, in consequence of the bleeding, several sittings may be required. The root should be carefully destroyed with some of the caustics. Perhaps of all these the most manageable is chloro-acetic acid, since its action can be stopped at once by syringing with warm water. Before any application is used, the surface should be most carefully dried with absorbent cotton-wool, so that the acid may not act on any part except the root. So long as this is done there is no pain, but the slightest touch of caustic on the exposed mucous membrane of the tympanic cavity is most painful, and is liable to set up considerable irritation. Indeed, the application of any caustic within the tympanum by unskilled hands is not free from danger.

A sharp-pointed piece of wood, or a few fibres of wool wrapped over the end of

a fine probe, are convenient for this purpose. After the growth has been thoroughly destroyed, the exposed surface of the tympanum should be protected from the air as in a case of ordinary perforation. Since polypi may become indirectly the cause of death, by preventing the escape of discharge from the tympanum, and so giving rise to blood-poisoning or meningitis, it is generally desirable to remove them as soon as they are discovered; but when the external ear is in a state of inflammation, and no urgent symptoms, such as pains in the head, are present, some delay may be allowed until the swelling of the canal has subsided under treat-

FIG. 14.—Wilde's Polypus Snare.

ment; for under such circumstances they cannot be entirely taken away, and interference at such a time is apt to excite rather than to allay the already existing irritation. Excepting under such circumstances, if the size of a polypus is such as to afford any impediment to the free egress of discharge, I cannot refrain from expressing the opinion that the risk of delay should in all cases be pointed out to patients. Within my own knowledge several deaths have occurred from meningitis which can be directly traced to a polypus blocking up the tympanum, and they took place in the case of patients who, with a full knowledge of the state of the ear, elected, contrary to advice, to put off the operation for a time.

Abscess in the mastoid process.—Communicating so freely as they do with the tympanum, and lined by a continuation of the same membrane, it is somewhat surprising that the mastoid cells should not more frequently become affected in the course of inflammation of the middle ear than they do. When they are inflamed, it is generally by extension from the tympanum; but I have very often seen abscess in the mastoid process, the tympanic cavity remaining meanwhile unaffected. Children are more liable than grown-up people to mastoid complications. With them intense pain, redness, swelling, tenderness, and oedema on pressure, are generally soon followed by fluctuation, and a free incision succeeded by a discharge of pus completes the list of symptoms, and necessary treatment. If considerable oedema, accompanied by constitutional disturbance, remains for several days even without fluctuation being discoverable, it is always more desirable to make an incision down to the bone, and break into the cells (which is readily done) than to delay the evacuation of pus. In the case of adults, however, although frequently a mastoid abscess is a simple affair, sometimes owing to the extreme thickness of the bone the matter cannot make for itself escape externally. The condition then becomes very serious. It is peculiarly characteristic of the presence of pus within the mastoid cells that the pain becomes agonising when the patients lie down. If this symptom has continued for some days, if there is constant pain and marked oedema on deep pressure, if the temperature is heightened, the tongue furred, and, lastly, if there has been a distinct rigor, no time should be lost in making an opening through the bone into the cells. To accomplish this, at the distance of about one-inch from where the ear joins the head, a long vertical incision is made down to the bone through the periosteum. A sharp-pointed perforator like a gimlet may be used, if no better instrument is at hand; but what is much preferable is a drill, the depth to which it is desirable to perforate being regulated by a moveable stop, so that the precise distance which is being bored can be seen. This requires to be considerable, and the bone is very hard. A probe should be, occasionally during the operation, inserted into the wound to determine if the cells have been reached. When this

has been accomplished, a few drops of fœtid pus will be seen to well up through the wound. The proceeding, which naturally requires to be conducted with considerable care, occupies some time, so that an anæsthetic must be employed. On the day after an operation, if the patient forces air into the middle ear, whilst both meatus are firmly closed, a quantity of discharge can be expelled through the opening. The complete relief which follows perforation of the bone, the subsidence of the urgent symptoms, and other general considerations which will at once suggest themselves, are sufficient without further comment to point to the extreme necessity for its employment under suitable circumstances. I have adopted this treatment in a great number of cases, and I feel justified in expressing the opinion that, if it is carried out sufficiently early, blocking of the sinus and its sequel of blood-poisoning may be frequently avoided.¹

Sometimes, instead of following the directions hitherto named, after suppuration within the mastoid process the purulent matter makes a route under the scalp or into the tissues of the neck. In such instances, when it is practicable, the most efficacious method of managing the case is to make use of a drainage-tube in such a manner as the condition may suggest.

Fatal results of inflammation of the middle ear.—It must be allowed then, whenever the lining membrane of the tympanum has become the seat of suppuration, there is a certain degree of danger to life from extension to the brain and its membranes, or from pyæmia; and if any part of the bone is diseased, the danger is no doubt much greater. This is shown by the results of post-mortem examination. But a large number of deaths occur in one of these ways when the bone is found to be perfectly healthy. If inflammation extends from the mastoid cells, it is more usual to meet with pyæmia than with cerebral abscess or meningitis. From my own observations, however, I feel confident that no rule can be laid down as to the direction which inflammation may take, should it start from the tympanum. When this happens, it is quite as common for a patient to die of blood-poisoning as from cerebral complications. In all cases the most premonitory symptom is a severe rigor. This is soon followed by an elevated temperature, increased frequency of pulse, furred tongue, and the usual indications of fever. When the brain or its membranes are affected, there is intense pain in the head, which continues until the patient finally becomes comatose. In meningitis the patient lies tossing his head from side to side, moans, delirium is a prominent symptom, and the course of the disease is generally rapid. But when an abscess forms in the substance of the brain, there is sometimes very little delirium, and the patient may linger for a long time, even for several weeks. The post-mortem appearances which are met with in this class of cases include the following:—Lymph or pus beneath the arachnoid, between the bone and dura mater, communicating with the tympanum. Pus passing from the tympanum into the labyrinth, through the internal auditory canal, and so to the cranial cavity; abscess in the substance of the cerebrum or cerebellum, the sac of which communicates with the tympanum or abscess in the substance of the brain with healthy brain tissue between the wall of the abscess and the temporal bone; blocking of the lateral sinus and jugular vein, accompanied with scattered abscesses in various parts, in the lungs chiefly, or pus in the pleural cavities.

In recalling to my mind, or referring to the notes of cases which I have seen, where death has occurred as a direct result of inflammation in the middle ear, it would not be difficult to divide them into two classes, very distinct in many ways from each other. In the smaller class of the two, the subjects have been apparently healthy, and without any affection of the ear until within a very few days of their death.

In consequence of a cold, or for some other reason not easy of explanation, they have been seized with acute pain in the ear, which has been soon followed in rapid succession by rupture of the membrane, discharge from the ear, rigors, and the constitutional symptoms just described. In the other and far larger class, there has been a perforation of the membrane, with more or less discharge from the ear, for many years. I have on several occasions known patients, who have been said to

¹ Vide *Med. Chir. Trans.*, vol. lxii.: 'Diseases of the Mastoid Bone.'

have had a discharge from the ear for over forty years, to be seized with a rigor, and die in the usual course without, so far as could be ascertained, any accidental cause which might excite fresh irritation in the tympanum. What happens on such occasions, irrespectively of any noticeable change in the state of the ear, may, in other cases to which reference has already been made, be traced to the blocking up of discharge by polypi, and this affords, if it were needed, an additional and urgent reason for the removal of these growths.

It must not be supposed that, in every instance where alarming symptoms show themselves in connection with a perforate tympanum, the termination is fatal. Intense headaches, attended with feverish symptoms, a rise in temperature, and cerebral irritation, are not very unusual with patients of this class. Under enforced quiet, leeches, and fomentations to the ear, these symptoms sometimes pass off and recur at intervals. The precise pathology of these cases becomes more clear from post-mortem examinations of persons who, with a perforation of the tympanum, have died from other causes. In these the dura mater overlying the tympanum has been found much thickened. Personal observation has for many years made me attach very great importance to pains in the head (often spoken of as neuralgic) with those who are the subject of perforations. Where there is evidence of diseased bone, as proved by examination with a probe, the importance is increased immensely. It would hardly be too much to say that these people are in great danger. In many instances where I have known the patients to die of cerebral complications, I have found a note of head pains, as having been complained of many years previously. Amongst those who have survived after complications of tympanic inflammation must be reckoned the recoveries from empyema, and pyæmic abscess in various parts of the body.

Perforation of the tympanic membrane is so common a disease, so many persons pass through long lives without any more serious trouble from the perforation than partial deafness and an occasional discharge from the ear during an ordinary cold, that the element of risk which surrounds the lives of the subjects of this lesion is apt to be disregarded, until attention is suddenly directed to the subject by the somewhat unexpected and generally unavoidably fatal termination of a case. It is impossible for anyone to have large numbers of cases of ear disease brought under his observation without a certain small proportion of them being composed of these fatal cases. Considering the frequency with which a perforation is found on examination to be accompanied with disease of the temporal bone, it is a matter of surprise that more deaths do not occur from this cause. There is no doubt that hundreds of persons in whom there is disease of the bone in that part which contains the tympanum, pass the chief part of a long life without any serious complication in consequence of it, whilst, on the other hand, at any moment, without any appreciably exciting cause, the train of fatal symptoms may commence. The same observation will hold good even when the perforation is uncomplicated with bone disease. Sea-water has a most irritating influence upon a perforation, and so often is the cause of an attack of inflammation in the tympanum, that everyone with this affection should be warned against sea-bathing. I have known several instances in which fatal symptoms would seem to have been excited by this irritant.

Malignant disease of the ear.—The history of malignant disease of the ear is the same as that of polypus, and the appearance which it presents in the early stages is precisely similar—a new growth originating from the local irritation of a purulent discharge from the lining of the tympanum. The form which it assumes is epithelioma. It is a somewhat uncommon affection; I have only seen three examples of it. In each of these large portions of the temporal bone were destroyed in the progress of a cancer. The immediate cause of death in two was exhaustion, in the other hemorrhage from the lingual artery. In the cases which have been recorded the discharge had lasted for many years. The single exception to them, so far as I know, was the second case which I saw, and in this the discharge had only been present for five months, and was originally induced by an accidental rupture of the tympanic membrane by a hair-pin. With a few of the patients only

whose cases have been placed on record a predisposition towards cancer could be said to have existed.

Necrosis and caries of the Temporal Bone.—As a result of inflammation in the tympanum and mastoid process, portions of the temporal bone may often suffer from necrosis and caries. The ossicles come away in the discharge, large parts of the external canal and mastoid die, and it is surprising to how great an extent this may happen without causing the death of the patient. On one occasion, after making an opening into a large fluctuating swelling over the mastoid process of a child, I readily removed with my fingers so large a piece of dead bone which was loose, that, upon examining it afterwards, it seemed to represent nearly the whole of the temporal bone. The wound healed, the external ear sank into the deep pit, which was left, and the child completely recovered its health.¹ It is also not at all unusual for large portions of the external auditory canal to come away or to require removal. The extent to which the hearing power becomes lost when the temporal bone is the seat of caries, depends of course upon the part of it which is affected. If that division which forms the cavity of the tympanum is involved, the deafness is very generally total, and the portio dura is paralysed.

SYPHILITIC AFFECTIONS OF THE EAR.

Inherited syphilis.—The occurrence of partial or complete loss of hearing in the subjects of inherited syphilis has become familiar to all since attention was first directed to it by Mr. Jonathan Hutchinson. It is most important that the ear should be examined in every case which presents itself, for it is quite possible that, unless this is done, the results of catarrhal inflammation, which may exist quite independently of syphilis in these patients, may escape observation.

Irrespective of such possible complications, a considerable number of the subjects of inherited syphilis become deaf. That the affection is strictly a nervous one may be shown from the fact that the hearing is occasionally entirely lost in the space of a few weeks, for there is no possibility of these symptoms existing to so severe an extent as a result of tympanic disease without absolute destruction of the tympanum and its contents, which would, of course, be recognised by the usual methods of examination. Whilst some become totally deaf from this cause, others retain, during their whole lives, a considerable degree of hearing power, and a period of several months is generally occupied before the greatest measure of deafness (whatever it may be) is reached. Usually the symptoms begin in early life, and sometimes in childhood; but adult life is often reached before the changes which produce it commence. What portion of the nervous apparatus becomes affected cannot be said to be accurately known; but the probabilities are strongly in favour of the cochlea being the seat of the disease. This presumption is likely to be correct, from the fact that in the commencement the very high notes are lost much sooner than ordinary sounds, such as the voice. As this affection of the ears is a very common one with children, it is frequently the cause of deaf-mutism.

Constitutional syphilis affects both the nervous and the conducting portions of the ear. During the course of secondary symptoms syphilitic patients very often become deaf, without any disease of the external or middle ear, and recover under constitutional treatment. The loss of hearing is symmetrical, and vibrations through the cranial bones are either heard badly or not at all. If the hearing becomes affected in the case of a person who, after having passed through the various phases of syphilis, is evidently not free from the disease after several years, it is scarcely ever regained, and is then most probably due to permanent intracranial changes.

In syphilitic ulceration of the fauces, the Eustachian tubes and tympanum sometimes become affected, and it then becomes necessary to employ the remedies suitable for catarrh, in addition to the ordinary constitutional treatment. In instances of this kind I have known the tympanic membrane to be ruptured, and the external

¹ Vide *Med. Chir. Trans.*, vol. lxii.

ear to be filled with syphilitic mucous tubercles. The same has happened on several occasions in the case of patients who, whilst suffering from a perforated membrane, have become syphilised. The ordinary purulent discharge from the ear having become imbued with the syphilitic poison in its passage over the meatus has caused the growth of the mucous tubercles. The local treatment is the same as when they appear in other parts.

DISEASE OF THE NERVOUS PORTIONS OF THE EAR.

Owing to the impossibility which exists of examining during life the nervous portions of the ear, the question as to whether they are in a state of health or disease must be settled chiefly by negative evidence and by the history of the case. This is not so difficult a matter as might appear at first sight. A patient becomes suddenly or gradually deaf, and suffers from tinnitus; if, upon examination, it is found that the external and middle ear are healthy, and if the vibrations of a tuning-fork cannot be heard through the cranial bones, it may be safely concluded that the disease is of a nervous character. Even when opportunities are given to examine the ears of persons deaf from nervous causes, and who have suffered severely from tinnitus, there is often no change which can be truly said to be of a distinctly definite character. This is not surprising when it is remembered that a complete loss of function in nervous tissue may exist without any absolutely discoverable alteration in its structure.

The morbid changes which have been noticed are chiefly hyperæmia of different parts of the labyrinth; supposed excess or diminution of otoconite, atrophy of the membranous labyrinth, chalky deposit in the meatus internus, atrophy of the auditory nerve. These conditions are of course quite exclusive of the congenital deficiencies in various portions of the labyrinth, which are met with in those who are born without hearing. Syphilis, blows on the head, and explosions near the ear have already been mentioned as immediate causes of failure in nervous function. There are several others which require notice. As is well known, it very commonly happens that the hearing is permanently and entirely lost during many of the fevers, no portion of the external or middle ear being at any time the seat of inflammation. The same occurs, not uncommonly, during an attack of mumps, when one or both ears may become affected to such an extent in the course of a few hours as to leave the patient absolutely deaf. This irremediable loss of hearing takes place in the case of young children with sufficient frequency to place mumps in the list of acute disorders which are the causes of acquired deaf-mutism.

Putting aside the circumstances which have already been mentioned as immediately attendant upon, and evidently as direct causes of nervous disease of the ear, there remain very large numbers which are, it must be admitted, more or less surrounded by obscurity. In order to, in some measure, dispel this, it seems to me, in the present state of our knowledge, there is nothing likely to prove so satisfactory as a careful attention to all the details in the history of every case which comes under notice. For anyone who will take sufficient trouble over a series of years, it would become quite possible to arrange cases into groups, each group having characteristics which make it quite distinct from the rest. A mental classification would be thus made by observing a uniformity in disease. It is to be hoped that the time is not far distant when each class will be found to be associated with a definite morbid change in some portion of the labyrinth or course of the auditory nerve. At present it is but a simple statement of the truth to say that this is not the case. What, it might be asked, is the precise lesion which accompanies complete or partial loss of hearing in persons of vigorous health when they are subjected to violent emotional influences? I have known a healthy woman to become instantly and totally deaf on the discovery of the unexpected death of her husband; the same to happen to a young girl on the receipt of a telegram informing her of the death of her father; to a mother on witnessing an accident to her child; or to a

woman on seeing the suicide of her husband ; to another on being frightened by an alarm of fire. Many other disasters might be named as having been instantly followed by extensive and permanent deafness. In a minor degree the anxious care and devotion with which some women watch and nurse their relatives during a long illness leaves occasionally, amongst other ailments, a loss of hearing and tinnitus; whilst in the case of men, prolonged mental strain is sometimes followed by the same symptoms.

Other examples of nervous disease of the ear belong to a class which have, for want of a name, and certainly for no better reason, as far as I can see, been termed *Menière's disease*; for, in the two cases related by Dr. Menière, and from which the name has been derived, both patients died (probably from pyæmia), and within the labyrinth the products of inflammation were found after death. In the cases to which recently the term has been applied, the patients do not die, nor do they suffer in health, except, in so far as it may be said to be affected by the temporary symptom of giddiness. An adult man, or woman, is seized with giddiness, and perhaps some vomiting. Severe tinnitus draws attention to one ear, which is then found to have extensively lost its hearing. An examination proves the external and middle portions of the ear to be healthy. The symptom of giddiness recurs frequently. If the patient attempts to walk, his gait is very unsteady.

This inability to walk without support occasionally lasts for many days, and even sometimes for weeks. After a time, with the exception of deafness and tinnitus, the unpleasant symptoms cease. These cases have received of late years considerable attention from physicians, and the complete absence of any danger to life is fully recognised. For some days after the attack, the patient should be kept in a recumbent position, as any attempt to walk is apt to bring on a fit of giddiness. The late Mr. Hinton and Dr. Hughlings Jackson have both carefully studied the manifestations of symptoms in these cases. In truth, this is the only way in which they admit of study, for the pathological condition which induces them is by no means determined. The experiments of Flourens, which at one time were thought to have settled the functions of the semicircular canals in regard to the maintenance of equilibrium of the body, have since been controverted, so that it seems improbable that this portion of the labyrinth is the seat of the lesion. As a matter of experience, when the giddy attacks cease the hearing suffers no further loss. Considering the association of vomiting with the giddiness, also the fact that irritation of the tympanum will often cause the patient to vomit suddenly without any feeling of nausea, that irritation of the pneumogastric nerve causes unsteadiness of gait as well as nausea or vomiting, and that the auditory and pneumogastric nerves are intimately connected at their origin, it seems quite possible that the giddiness and sickness in these cases may be due to reflex action of the pneumogastric, excited by some lesion situate on the course of the auditory nerve, or to some disturbing cause at the point of origin of these nerves. Any explanation amounts to nothing more than conjecture. This observation is equally applicable to tinnitus, which occurs so frequently in all nervous affections of the ear. We know that any pressure on the labyrinth will excite it. A piece of cerumen in contact with the tympanic membrane, and so acting through the chain of ossicles on to the stapes, causes tinnitus. So, for the same reason, will any pressure within the tympanum; the removal of the cause in each case being instantly followed by cessation of the symptom. When, however, it is present without any discoverable change in the ear, it can be regarded as nothing more than a symptom, and a very constant one too, of disturbed function. If we consider for a moment that an overdose of quinine is enough to excite it, it is not to be wondered at that an absolute reason for its existence often cannot be given. There is perhaps no kind of noise to which tinnitus has not at some time been compared by those who have suffered from it, and in extreme cases it gives far more distress than the loss of hearing.

The hearing becomes affected in some young women at the birth of their children, and it may then generally be predicted that each successive confinement will be followed by a still further degree of deafness, which seems to be increased very much

if the children are nursed by the mother. In these cases there is also considerable tinnitus. Indeed this symptom, often so difficult of explanation, is almost always present when the perceptive power of hearing is at fault. Some people who suffer for years with tinnitus, which resists all treatment, suddenly lose it without any more assignable cause for its departure than for its advent. Perhaps in the instances referred to where the hearing in women becomes affected about the time of a confinement, the change is due to mental causes. It is certain that the emotions have a most remarkable and decided influence upon the hearing, and probably more than on any other special sense. I have frequently known the hearing to be suspended in a great measure for days at a time under the influence of some circumstances which caused great mental suffering. These cases are allied to, though not precisely like, those in which, as previously mentioned, the occurrence of the deafness was sudden and lasting. It seems reasonable to conjecture that, whatever may be the nature of the change, it is central, rather than situated within the labyrinth.

The much-discussed question of why a certain number of persons, in whom the hearing is defective, can hear better whilst loud sonorous vibrations are going on around them, has received at various times many explanations. Some of these, of the most ingenious and plausible character, are inconsistent with the fact that the peculiar symptom is undoubtedly present when the history and an examination of the ear prove that the middle ear is absolutely healthy. It is difficult, then, to accept any theory which presupposes morbid change within the tympanic cavity, or in the substance of the membrane. On the other hand, it is true that this phenomenon is often present where there has been long-standing catarrhal disease of the middle ear. Still, in practice, it is not unusual (indeed it is very common) to meet with cases in which there are two distinct elements—viz. disease of the conducting apparatus, and, superadded to this, symptoms of so markedly nervous a character that they are independent of the failure in the conducting apparatus. I prefer, therefore, to offer no decided opinion in explanation of the fact that some persons in whom there is tympanic disease, and some in whom there certainly is not, can hear better in a noise (such as being in a railway carriage, standing by a waterfall, or in a manufactory amid the sounds of looms and other machinery). That this increase in the capacity of hearing is real, and not imaginary, can be readily shown by tests with some constant sound. All observers are agreed that this symptom is an unfavourable one in regard to the recovery of the hearing at any time. Amongst the first signs of the loss of hearing, due to the degeneration which accompanies old age, is the inability to hear very high notes. The whistle designed by Mr. Francis Galton for testing the range of hearing in animals will demonstrate this. A similar inability to hear very high notes often accompanies obscure nervous affections of the auditory apparatus.

There are within my knowledge a certain number of families in which for several generations there has existed a predisposition to lose the hearing. In examining many of the subjects of this malady, I have been unable to detect any change in the conducting portion of the ear, or to elicit any history of catarrh. It seems fair, therefore, to infer that a tendency to lose hearing power may be inherited—at least, this is an impression which amounts to a conviction with me.

W. B. DALBY.

AFFECTIONS OF THE MUSCULAR SYSTEM.

ALTHOUGH muscles are so much exposed to accidents and violence, they are not readily injured; nor, considering their high organisation, are they frequently the seat of disease. Muscles may suffer from contusions, strains, rupture, and wounds of different kinds. Severe contusions are frequently followed by temporary loss of power in the muscle; this, together with the extreme pain in any attempt to move the part, particularly in the neighbourhood of the large joints, sometimes leads to the suspicion of more serious injuries, as fracture or dislocation. Strains of muscles are often followed, especially in later life, by pains of a lasting and troublesome character, partaking of the nature of rheumatism. Muscle may be ruptured either from external violence or from the too energetic action of its own fibres; this latter occurrence is by no means a common one, especially that in which the entire muscle is torn across. In the living body, muscle offers a greater resistance to a force tending to rend it than either tendon or bone; and when it does give way, it is for the most part at its point of junction with the tendon. Sédillot¹ says that in twenty-eight cases of rupture of muscles, thirteen were ruptured at this point.

The power of resistance in a sound and healthy muscle in a state of full tonicity is enormous; and many interesting comparisons and calculations on this subject will be found in Borelli, *De motu Animalium*. Percy² relates the case of a person with wry neck, who was suspended by the head, with a view of putting the muscle on the stretch; the result was separation of the muscle from its insertion, but no laceration of its fibres: and in a case in which the thumb was torn off, the tendons were drawn out, but the muscles were left uninjured, except at the point of junction with the tendon. We are all familiar with the fact that the tendon of the rectus femoris and the tendo Achillis give way rather than the fibres of their respective muscles. With the loss of its vital contractile power, muscle loses its advantage over tendon, and the experiments of Richerand and others fully establish the fact that after death muscle is more easily ruptured than tendon. We observe this when a limb is forcibly straightened from the bent position after the muscles have become unusually rigid from convulsions before death; here laceration of the muscles, and not of the tendons, takes place.

Though muscle in the living body is not often ruptured, yet cases of this injury occur sufficiently often to have given most of us one or more opportunities of witnessing it. Sédillot has recorded no less than twenty-eight cases of entire or partial spontaneous rupture of muscles; but he observes, that no voluntary act can occasion a rupture of their fibres, however powerful the effort may be, and this for two reasons: 1st, because, under the influence of the will, all the fibres of a muscle, and the muscles associated with it in its action, contract uniformly, simultaneously, and in a regular order, to overcome a resistance; and 2ndly, because at the moment that the will perceives that the power opposed to it is greater than its efforts can overcome, it ceases to strive further. Rupture, therefore, can only take place when, in some involuntary or instinctive effort, as in the endeavour to recover the equilibrium in a false step, or from some similar cause, the whole force is thrown in a violent and unexpected manner upon one or two muscles, or even on a few fibres. Among the cases collected by Sédillot, is one in which the rectus femoris was ruptured. In

¹ *Mém. sur la Rupture musculaire*; *Mém. et Prix de la Soc. de Méd. de Paris*, 1817, p. 115.

² *Journal général de Médecine*, vol. lxi.

another case, the psoas magnus muscle was found ruptured after death, the patient having died from inflammation and suppuration following the accident. The complete rupture of the biceps muscles of each thigh occurred in a man falling from a height; and the two recti abdominis were torn across at their upper part in a young man, in the struggle to save a tray of cement as he was falling from a platform.

Rupture of the adductors of the thigh may also occur in the effort of riders to recover their balance when their horse makes a sudden and unexpected start to one side. But perhaps one of the most frequent injuries of the kind is that of the extensor brevis of the foot, due to turning the ankle under, as it is called. Here the contracted ends of the torn muscle may be easily felt, as well as the collection of blood between them.

It more frequently happens that a few fibres only of a muscle are ruptured, and this usually occurs in the gastrocnemius.¹ Muscles are sometimes torn across in violent paroxysms of muscular spasm, as in tetanus or vomiting. In these cases the ends of the muscle, from the violence of the retraction, are thrown into considerable swellings.

In a case of acute traumatic tetanus, under Larrey, the man was immersed in cold baths, after each of which the convulsions and muscular contractions were most severe, and he died in three hours; a swelling, however, had been previously observed below the umbilicus, on the right side. On a post-mortem examination it was found that the tumour was occasioned by the retracted ends of the rectus, which was entirely torn across. The space between the two ends of the muscle was filled with blood. Mr. Curling describes a case in which portions of both recti abdominis were ruptured by tetanic convulsions (one of the specimens is in the Museum of the College of Surgeons). Mr. Gray exhibited, at the Pathological Society, the rectus muscle of a patient who had died of tetanus, in whom almost complete transverse laceration of the muscle had taken place. In Mr. Earle's case of tetanus, described in *Med. Chir. Trans.*, vol. vi., one of the psoas muscles was partially ruptured. Boyer relates the case of a strong man admitted into La Charité with 'bilious fever;' an emetic was given him, and whilst vomiting, acute pain was felt a little below the middle of the left rectus abdominis muscle. On examining the part, there was neither tumefaction nor discoloration of the skin, but an indentation, into which the fingers could be placed, was felt. The man died; and the muscle was found completely torn across, the two ends being an inch apart, and the space between filled with blood. Another case of the same kind has recently been observed at the Middlesex Hospital.² And in the case of a young woman who died at University College Hospital during an attack of severe vomiting, and on whom I performed a post-mortem examination, the only lesion found to account for the sudden death was rupture of the œsophagus into the left pleura, just above the diaphragm. The specimen is preserved in University College Hospital Museum. Mr. C. Holthouse relates an interesting case of tear of the rectus abdominis in a man who, to save himself from falling, caught at part of a scaffolding, and hung suspended for a time until rescued, when the muscle was found to be torn. He had felt the giving way most distinctly.³

The rupture of a muscle is accompanied by extreme pain, resembling that occasioned by a smart blow from a whip or stick, and often by a distinct sound like the snapping of a cord; all motion of the part is either impossible, or is accompanied by such severe pain, with spasmodic twitching, as to cause the patient to desist. If the muscle be a superficial one, a deep indentation will be found at the seat of rupture, produced by the retraction of its divided ends; and often a considerable swelling, proportioned to the vigour of the contraction of the torn fibres, as in tetanus; and as there is always extravasation of blood, much discoloration of the skin will follow. The indentation and extravasation are not apparent, however, in ruptures of the deep muscles, by which their diagnosis is rendered less clear. If the rupture be discovered early, and judiciously treated, a sufficient approximation of the divided ends will result, good union will follow, and the function of the muscle will be restored. If, on the other hand, it be overlooked or maltreated, or if it occur in a part where proper measures cannot be employed to approximate the ends of the muscle, as in some parts of the trunk, in ruptures of the deep muscles about the hip and shoulder, &c., it will be found that a wide separation exists, and that the ends of the muscle, instead of uniting, have become attached to the parts in the immediate neighbourhood, and the use of the muscle is consequently lost.

¹ Wardrop, *Med. Chir. Trans.*, vol. vii.

² *Lancet*, 1882, p. 687.

³ *Path. Soc. Trans.* xiii. 203.

The treatment consists, 1st, in placing and retaining the part in the position most favourable for relaxing the muscles; and, 2nd, in approximating the separated ends to one another by even compression, which we know exercises so great a power in controlling and modifying the excess of contraction in the muscles, in fractures, &c. As regards the first, this is easily accomplished in the limbs: thus in rupture of the rectus femoris the knee is straightened, and the limb is raised to an angle with the body, as in fractured patella; but where the rupture occurs in the trunk, this cannot be done so readily; yet in a case already alluded to, in which both recti abdominis were ruptured, a good union was effected by keeping the patient in a sitting posture, the body being bowed forward, together with proper bandages.¹ The second is accomplished by an even and uniform compression of the muscles by means of carefully-applied flannel bandages, or laced belts, aided in some cases by a strip of leather or gutta-percha. In addition to these measures, bromide of potassium may be freely administered internally to aid in the relief of spasm. At the end of from a fortnight to three weeks, the union is generally completed. The process of union is similar to that of other structures; the effused blood is absorbed, plastic lymph is poured out, which assumes by degrees the firm and resisting character of tendon, muscular fibre itself being never reproduced. When a muscle, with the integument and parts around, is divided, it retracts to a greater extent than where the muscle alone gives way, from being deprived of its collateral support. This, in conjunction with an open wound, renders it extremely difficult to approximate the retracted ends of the muscle, and to find means for retaining them in a proper position; hence it will be found that wounds extending through muscles are followed by nearly complete loss of use in the latter, the great chasm between their ends being filled up by granulation. It is recommended to endeavour to bring the ends together by sutures with all antiseptic precautions both before and after the operation. These measures, with position favourable for the approximation of the ends, and such encircling supports as can be employed where a wound is present, may do much towards restoring the muscle to a certain amount of usefulness.

Inflammation of muscle.—Inflammation of muscle, or Myositis, may be primary or secondary, and may be due to a variety of causes, operating from without or from within, and may be met with in every degree, from slight congestion to free suppuration. Those causes which operate from without are blows, strains, or other forms of violence. Those operating from within are rheumatism; the various septic conditions of the blood coming under the head of septicæmia and pyæmia (*vide* PYÆMIA, vol. i.) and also the vicinity of other inflamed parts.

Myositis from injury, unless the latter have exposed the tissue to the entrance of impurities, is usually of the plastic kind, and runs its whole course as a rule without suppuration. It commences as a simple hyperæmia of the vessels of the part, and may never advance further, usually subsiding before long. In more severe cases there is plastic exudation into the interstitial connective tissue, with proliferation of the corpuscles of the latter. It is still sometimes questioned whether the muscle corpuscles also participate in the plastic change, but it is almost proved that they do.² The plastic matter thus formed usually organises after a longer or shorter period (in healthy cases) into fibrous tissue, which takes the place of the original muscle fibres in the form of a white knot or band. If the process be more acute, the exudation and proliferation exceed the bounds of plastic change and produce pus. This makes its way to the surface if in large amount, and is discharged; if less abundant, it may be completely or partly absorbed, leaving a little caseous matter behind. In either case a scar of fibrous tissue remains at the seat of inflammation which is never replaced by muscle fibres. Occasionally a deposit of calcareous material takes place at the seat of old inflammation forming larger or smaller nodules.

Myositis due to causes operating from within is very frequently suppurative. This does not hold good of the rheumatic form, but with the various kinds of septic disease does so. Whatever be the irritant in rheumatism, it leads only to a chronic

¹ Richerand, *Nosograph. Chir.* vol. ii.

² Cornil et Ranvier, *Man. d'Hist. Path.* 2nd ed. p. 533.

hyperplasia, resulting in thickening of the connective tissue of the muscles, with consequent impairment of their functions. But in the septicæmic inflammations it is almost the rule for pus to form. This may collect in smaller or larger accumulations in any of the muscles of the body. In the deeper parts its existence may not be easily proved, but superficially there can be no difficulty in detecting the condition.

The local subjective and objective symptoms of abscess in muscles, whether caused by external or internal agencies, are generally much alike. There is local pain, much aggravated by any movement of the part, also heat and throbbing. The muscle is usually contracted to a considerable extent and rigid, feeling hard and firm to the finger. The part of the body in which this contraction takes place is correspondingly deformed more or less, often to an extreme degree if it be a limb; there will also be œdema around, and a blush in the skin in the case of superficial muscles.

The treatment of this condition in its earlier stages will consist in leeching in simple cases, followed by hot fomentations, and the application of belladonna extract mixed with glycerine, while the part is kept at complete rest. Later when pus is manifestly increasing, a free evacuation of the abscess by aspiration or incision under the strictest precautions as to cleanliness will be called for.

After such an abscess has healed, the muscle is frequently left in a contracted condition, which will require both passive and active exercise for its removal. The inflammatory material spread through the parts around will be gradually absorbed, and probably nothing but a small contracted fibrous scar remain.

In that form of myositis due to sepsis the internal use of quinine in free doses, or of the salicylates, with abundance of stimulants, is called for.

Tertiary syphilitic change, having many features in common with inflammation, will be last considered here. One of the first in this country to describe its effect on muscle was Mr. Tatum, in a paper read before the Royal Medical and Chirurgical Society, in January, 1845,¹ in which a group of three cases, two of which were associated with other symptoms of constitutional syphilis, was described, whilst the history of the third case was obscure. The disease, which he had not seen alluded to before, appeared in the form of rounded enlargements in the left sterno-cleido-mastoid muscle; there were three swellings in two of the cases, and two only in the other; in one of these there was also an enlargement in the tendinous origin of the part; the tumours were evidently formed in the substance of the muscles, and were nearly of the size of a pigeon's egg, and gave the latter a singular headed appearance; there was stiffness, with much tenderness, in the part, and great pain when the muscle was in action; the skin was neither adherent nor discoloured; the disease was slow in its progress, and had remained nearly stationary for some months. All the cases occurred in females, probably from the neck being more exposed than in men, in each case the effects of the iodide of potassium were manifest. In the first case the patient obstinately refused to take the drug, in consequence of which mercury and various other remedies were tried without any good effect. After some time she consented to take the iodide of potassium; from two to three grains were administered thrice daily, while the iodine ointment was applied externally; the tumours soon began to diminish, and in less than six weeks completely disappeared. The other two cases were similarly treated, with complete success; but in one of them the patient was obliged to lay aside the remedy for a time, during which it was remarked that the tumours became stationary; on her resuming the medicine, however, all remains of the disease quickly left her. What constituted the swellings could not of course be ascertained from these cases; but a case occurred some time after, in which there was a tumour in the middle of the biceps muscle, so hard and defined as to induce the surgeon to proceed to its removal by operation, when, on cutting into the fibres of the muscle, no tumour was visible, but the muscle in that part was congested and infiltrated with a greyish kind of lymph, great part of which oozed away with much blood, all the swelling subsided, and the wound healed, leaving no enlargement. Much light has been thrown upon the nature of the gummatous deposits of late, and their ubiquity has been fully demonstrated. It is unnecessary,

¹ *Lancet*, vol. i. 1845, p. 136.

therefore, to describe their structure in muscle specially, further than to say that they infiltrate this tissue as elsewhere, and undergo the same secondary changes. Thus they may be rapidly absorbed under treatment, leaving no trace behind of shrinking or induration: they may undergo fibrous, fatty, or calcareous degeneration, or, approaching the surface, may thin and break the skin, and then undergo softening and liquefaction, leading to deep ulceration and loss of tissue. I have this day treated a case in which, together with a breaking-down gumma over the sternal insertion of the sterno-mastoid muscle, there was a second well-defined gummatous mass in the body of the muscle higher up, which gave no trouble and showed no signs of inflammation.—[A. E. B.]

Sometimes there is a *simple contraction*, or shortening of a muscle, without apparent alteration in its structure or change from its normal condition, as an occasional effect of the presence of syphilitic poison in the system, and is usually found in the muscles of the arm or fore-arm. M. Ricord has noticed this so long ago as 1842.¹

M. Notta, in an interesting paper on Syphilitic Muscular Contractions,² gives three cases, the features of which were much the same; and in each the biceps was the seat of the contraction. There was no hardness or rigidity of the muscle when not in action; the pains were variable, being great on putting the muscle on the stretch, and mostly referred to its insertion. The contraction was slow, and gradually reached a certain point, causing fixed flexion of the elbow. The iodide of potassium, with minute doses of the proto-iodide, appears to have cured every case. The same may be said of the cases cited by Ricord³ and others, in which there was a certain change of structure of the muscle, associated with contraction. As a general rule, mercury has done no good; in fact, in many of the cases the disease appeared to increase while the patient was undergoing a course of the drug.

Muscular atrophy.—Muscular tissue is frequently subject to atrophy, which may consist of one or more of the following alterations:

1. Simple atrophy.
2. Atrophy with granular degeneration.
3. Atrophy with fatty degeneration.
4. Atrophy with (the so-called) waxy degeneration.

In *simple atrophy* the degree of wasting of the muscular tissue varies considerably. Generally, the fibres, although paler and reduced in diameter, retain their anatomical characters. The transverse and longitudinal striæ are well marked, the sarcolemma preserves its usual delicate and transparent appearance, and the nuclei it contains are not increased in number. Such is the form of atrophy met with in chronic and exhausting diseases; in cerebral paralysis; after contusions, compressions, and affections of the joints. In many diseases, however, both acute and chronic, simple atrophy, or wasting of the muscular fibres, is accompanied, in a greater or less degree, by one or more of the degenerations above mentioned. Such is sometimes the case after acute fevers, particularly typhus or typhoid; after alcoholism, lead-poisoning, rheumatism, &c.

But there is another form of this malady, which is known by the name of *progressive muscular atrophy* (Crucilhier), *atrophie musculaire graisseuse progressive* (Duchenne), and *wasting palsy*. This curious disease differs in several respects from the atrophies above mentioned. It is always chronic, but of uncertain duration; is frequently hereditary; is capricious or irregular in its invasion; prone to spread from one part to another, or become general, and thus go on to a fatal termination. The affected muscles suffer different degrees of wasting, and assume a variety of aspects. Even in the same muscle, bundles in different stages of atrophy and degeneration may be found at the side of others that have retained their normal state. When the wasting is extreme in all the bundles, a long muscle may be reduced to a mere fibrous and cylindrical cord, or to a kind of tendon, and a flat muscle may be reduced in the same manner to a kind of membrane. In some instances the atrophy may be *simple*—that is, the muscular tissue may be wasted

¹ *Gaz. des Hôpitaux*, p. 98.

² *Archives générales de Médecine*, 4^e sér., vol. xxiv. p. 413.

³ *Gaz. des Hôpitaux*, 1840, p. 1.

to a considerable degree without any granular or fatty degeneration; but, generally, one or both of these alterations of structure is found to exist to a greater or less extent. The muscle also changes and varies in colour according to the nature and degree of the atrophy. It is paler than natural; occasionally it is quite colourless, like the flesh of fish; or it may have a faint yellow or ochreous tint. Its consistence for the most part is increased in consequence of the increase of the interfibrillar connective tissue. When examined under the microscope, the affected muscles may be seen to have lost to a variable extent and degree, or even entirely, the appearance of transverse and longitudinal striation, while in a corresponding proportion the sarco- or muscular element is transformed into granules, which, in some instances, are too fine to be distinguished as separate particles. The granules are soluble in acetic acid.

Granular degeneration or disintegration of the muscular tissue may exist alone; but frequently it is accompanied by fatty degeneration, or may only form the first stage of the latter change.

Fatty degeneration.—This morbid process may make its appearance in the muscular tissue at once; or, may follow, accompany, and altogether replace the granular change. Besides this transformation into fatty particles, fat-cells in unusual, and sometimes in great numbers, are found between the fibres, either collected into groups, or disposed in linear succession, like rows of pearls. These cells multiply in proportion as the muscular tissue disappears, so that, when the fibres are reduced to mere filaments, there may be no loss of volume in the limb. An interesting case of this description is related by Mr. Hallett.¹ The degenerations seemed constantly to have commenced on the surfaces of the muscles, and extended inwards to their centres; so that many which appeared wholly converted into fat, exhibited, in their interior, muscular fibres in a more or less healthy condition.

Waxy or vitreous degeneration.—This structural change was first described by Zenker.² It is called by the French pathologists, *vitreous* degeneration.³ According to Zenker, it is observable only in the voluntary muscles, and never attacks all the bundles of the same muscle. The essential change of structure consists of a transformation of the muscular tissue into a homogeneous, colourless, and glistening substance, in which the transverse and longitudinal striae, together with the nuclei, have entirely disappeared. This kind of degeneration is more common after acute diseases, particularly after typhus and typhoid fevers, but occurs also in *progressive muscular atrophy*. Indeed, in this peculiar malady, all the three kinds of degeneration—the *granular*, the *fatty*, and the *vitreous*—may be seen, not only in the same patient, but in the same muscle.⁴

In a large majority of instances, *progressive muscular atrophy* first makes its appearance in one of the upper extremities, especially in the right limb. It begins commonly in the muscles of the hand, first in the thenar eminence, then in the hypothenar, and next in the interossei. When the interosseous muscles are considerably wasted, the hand assumes the appearance of a bird's claw—the *main en griffe*, as it has been termed by Duchenne. If the atrophy extends upwards, the flexors and extensors of the fingers, and sometimes the muscles at the back of the forearm, become involved. When the disease extends beyond these limits, it attacks the muscles of the arms and trunk; the biceps first, then the deltoid and the triceps, the pectorals, the latissimi dorsi, the rhomboidei, the extensors and flexors of the head, the sacro-lumbales, the abdominal muscles, the muscles of respiration and deglutition. Occasionally the depressor muscles of the jaw become involved. In some instances the atrophy is limited to the muscles of the forearm, and in others it begins in the muscles about the thorax, and makes considerable progress, while the arms remain unaffected. Sometimes it extends to the lower extremities, but rarely begins there.

⁴ Charcot et Joffroy, *Archives de Physiologie normale et pathologique*, 1869, No. 3, p. 363

The unequal and irregular wasting of the muscles produces in the trunk and limbs a variety of alterations in their shape and position, which are characteristic of the disease; for in ordinary atrophy succeeding exhausting diseases, the emaciation is uniform, as it affects nearly all the muscles of the part to the same extent.

The earliest symptom of progressive muscular atrophy is a loss of muscular power in the afflicted parts, especially after exercise or exposure to cold. With this weakness there is an awkwardness in the patient's movements, and a certain loss of muscular co-ordination, arising from the unequal or irregular wasting of the muscles, and the consequent change in their relative force or antagonism when employed in the performance of voluntary movements. Among the other early symptoms are cramps, twitches, and fibrillary tremors in the muscles. Generally the sensibility remains unimpaired, but occasionally there is numbness of the skin, or a certain degree of cutaneous anesthesia; while, on the other hand, in about half the cases, more or less pain is experienced in the wasting muscles, or previous to their atrophy. Occasionally there is a general rise of temperature, especially in the earlier stages of the disease.¹

Pathology.—Cruveilhier, who was the first to investigate the morbid anatomy of progressive muscular atrophy, believed that atrophy of the motor nerves was the starting-point of the disease. This opinion was founded on eleven cases in which the motor nerve-roots were more or less wasted. But in the majority of instances in which post-mortem examinations were made, no appreciable alteration of the nerve-roots was discovered. It was therefore inferred that atrophy of the nerves cannot be the actual cause of that state of the muscles; and since no disease of the nervous centres had hitherto been detected, it was further inferred and generally believed that progressive muscular atrophy is a disease originating in the muscles themselves, in consequence of impaired nutrition, resulting from a peculiar diathesis of an hereditary tendency. The more recent supporters of this view were Trousseau, Duchenne, Meryon, Roberts, Oppenheimer, Friedberg, Hasse, Friedreich, Cohn, and others. But in 1861 Dr. Lockhart Clarke discovered in the spinal cord removed from a well-marked case of progressive muscular atrophy, numerous lesions of the grey substance, consisting chiefly of areas of what he called granular and fluid disintegration.² In several other cases which he subsequently examined, the same kind of lesions were observed in company with similar alterations of some of the white columns, with dilatation of blood-vessels, or atrophy of the nerve-cells and of the anterior roots of the nerves.³ Since his first publication on the subject, several German and French pathologists, by means of improved methods of observation, have obtained similar results.⁴

The local changes in the muscles may be briefly described as consisting in 'chronic myositis, interstitial proliferation of connective tissue with secondary destruction of the muscular fibres, and finally fibrous degeneration.' The disease consists then in an essentially inflammatory process, a '*polymyositis chronica progressiva*.'⁵

Etiology.—Among the predisposing causes of progressive muscular atrophy, consanguinity, or hereditary influence, is universally acknowledged to hold the first rank. Dr. Roberts collected the history of ten families in which muscular atrophy prevailed, and of these, twenty-nine individuals were attacked. Aran relates that a sea-captain had lost two maternal uncles and a sister by this disease, and that another patient's two aunts had died from the same malady. Meryon's first cases were four boys who had six healthy sisters.⁶ In another family two boys were affected while

⁶ These interesting cases, with the microscopic appearances of the muscles, are recorded in vol. xxxvi. of the *Med.-Chir. Trans.*

the two sisters escaped. The male sex is therefore much more prone to muscular atrophy than the female—in the proportion of about six to one. In nearly all the hereditary cases on record, the disease became generalised, and therefore tended to a fatal termination.

Among the chief exciting causes are excessive muscular exertion, cold and damp—especially when combined—and injuries or diseases of the spine. In those cases which are attributable to the influence of cold and wet, the atrophy is generally preceded and accompanied by neuralgia or so-called rheumatic pains in the affected muscles, or in the course of the nerves leading to them. Syphilis, again, appears to be one of the assignable causes of the disease. To this form M. Rodet has given the name of *atrophie musculaire progressive syphilitique*.¹ In some instances no particular cause can be clearly assigned, and these are the cases in which hereditary influence appears to come into operation.

Treatment.—This must of course depend, to a certain extent, on the causes to which the disorder may be reasonably traced. Removal from the influence of cold and damp, or avoidance of undue muscular exertion, is of primary importance. Warm and sulphur baths, especially those of Aix-la-Chapelle, have been particularly recommended. When there appears good ground for believing that the atrophy is attributable to syphilitic taint, iodide of potassium, or perhaps mercury, must be employed. In cases attributable to other causes, vegetable and mineral tonics, cod-liver oil, and phosphorus may be administered. Dr. Meryon speaks very highly of the long-continued use of arsenic. But of all remedies hitherto employed, galvanism is undoubtedly the most useful, when applied to the affected muscles. Regular gymnastic exercises are also recommended by those who have had most experience of the disease. The benefit derived from it, however, is very often temporary. Remak strongly recommends the application of the constant galvanic current to the spinal column, particularly in the cervical region. The fact, as already stated, that in the advanced stages of progressive muscular atrophy, various lesions have been found in the spinal cord, would suggest the propriety of trying the effects of counter-irritants, particularly setons and blisters to the spine, in the early stages of the disease.

There are two other special forms of muscular atrophy, which are peculiar to the period of childhood, viz., the atrophy which follows infantile paralysis, and the degeneration of muscles with apparent hypertrophy or pseudo-hypertrophic paralysis.

1. The muscular atrophy of infantile paralysis is extremely interesting to the surgeon, in consequence of the deformities which it so frequently occasions. The period of childhood at which this disease makes its appearance varies from a few months to a few years after birth, more especially during the first dentition. The attack is generally sudden, and frequently preceded by a feverish state which may last a few hours or a few days, accompanied occasionally by convulsions, which are immediately followed by paralysis without loss of sensibility. The paralysis generally begins in the lower extremities, but rarely attacks the upper extremities alone. At first it is more or less general, but after a variable period it restricts itself to particular muscles, or groups of muscles, or to a particular member, and thus becomes localized. The muscles upon which it most frequently fixes are those at the anterior part of the leg—the extensors of the toes, and flexors of the foot; the extensors and supinators of the hand; the extensors of the leg, and muscles of the foot. Sometimes single muscles are affected, and most commonly, the extensor longus digitorum of the foot, the tibialis anticus, the deltoid, or the sterno-mastoid. Occasionally, but rarely, it is observed to affect the serratus magnus, producing a remarkable deformity of the scapular borders. After a time, varying generally from one to two months, but sometimes much longer, the paralysed muscles begin to waste, and may ultimately be reduced to mere fibrous bands. Laborde relates a case in which considerable atrophy of the deltoid muscle occurred in four days after the first appearance of the paralysis.² Nor is the atrophy confined to the muscles; it involves

¹ *L'Union médicale*, No. 26, p. 403, 1859.

² *De la Paralyse (dite essentielle) de l'Enfance*, p. 45.

the bones, ligaments, and other parts. Together with these grosser changes are associated others more minute in the spinal cord. These consist in sclerosis of the anterior cornua of its grey matter. This change, according to Charcot, is due to an inflammation affecting isolated groups of ganglionic cells, others around being unaffected. Some of these groups may recover, while many are destroyed, explaining the partial recoveries familiar to us.¹

The paralysis and the atrophies by which this disease is succeeded combine to produce a variety of deformities and unnatural attitudes which call for the surgeon's skill, either in the application of mechanical apparatus, or in the performance of necessary operations. These deformities consist chiefly of *talipes equinus*, *equinovarus*, *equino-vulgus*, *calcaneus*, or *calcaneo-vulgus*, and *talipes varus* (vide ORTHOPEDIC SURGERY).

The paralysis itself and the muscular atrophy to which it gives rise are not often fatal. The difficulty in treatment consists in restoring the muscles to their normal condition; but this, in many instances, may be accomplished. The remedies recommended by the most experienced practitioners consist of nux vomica, strychnine, cod-liver oil, the preparations of bark and iron; sulphur and salt-water baths; blisters and counter-irritants along the spine; stimulating embrocations to the affected muscles, and especially the application of electricity.

2. *Degeneration of muscles with apparent hypertrophy*.—This peculiar disease was first understood and diagnosed by Dr. Duchenne (of Boulogne) in 1838. Since then it has been recognised and investigated chiefly in Germany by Griesinger, Eulenburg,² Cohnheim, Berind, Wernich, Oppolzer, Heller, and Seidel. It begins in childhood, like the malady just described, but often continues up to an advanced period of youth, when the patient is cut off by some intercurrent disease. Its course may be divided into three stages; one of partial and incomplete paralysis; one of apparent muscular hypertrophy; and, lastly, one in which the paralysis becomes general, and the muscles waste. Eulenburg states that of 86 there were 70 males and 16 females=9:2. Again, out of 80 cases clearly recorded, it began before the fifth year in 45; between the sixth and tenth year in 22; between the eleventh and sixteenth 8 times. Only 5 times was it observed to commence in later life, viz., in men and women at the ages of 26, 30, 40, 41, and 43 years.

The first stage begins with weakness of the lower extremities, either before or after the period at which the child should be able to walk. In the former case, when the little patient attains the age of ten or twelve months, and attempts to move about or stand, it falls immediately, and continues unable to walk, even when assisted, for two or three years.

The second stage begins some months—or even as long as two years—after the muscular weakness, and is manifested by a progressive enlargement of the gastrocnemii, then of the glutei and lumbar muscles. This enlargement occurs sometimes in nearly all the muscles, but in general it is limited to a few. The enlarged muscles are firm and elastic, and become very hard during contraction. This condition may remain stationary for some years.

In the third stage the paralysis gradually increases and becomes more general. The patient is no longer able to stand upright; the upper extremities become affected; the enlarged muscles rapidly decrease in volume; and the limbs and trunk become atrophied *en masse*. In this state the patient may exist for a considerable time, but ultimately dies by intercurrent disease. Many of the children afflicted with this singular disorder have dull intellects, and are occasionally more or less idiotic.

The morbid anatomy of this disease has been investigated chiefly by Duchenne in France, by Eulenburg, Cohnheim, Griesinger, and others in Germany, and recently by Gowers in England, who has published a most complete essay on the

¹ Wilks and Moxon, *Path. Anat.* p. 251.

² Ziemssen's *Cyclop.* vol. xiv. p 10.

subject.¹ Nothing abnormal has been discovered in either the nervous or vascular systems. Eulenburg and Cohnheim found the electro-muscular contractibility everywhere perfect. To the touch the muscles gave the sensation of a doughy and inelastic mass. They were marked with stripes of a yellow or yellowish-white appearance. At certain points they could not be distinguished by the naked eye from the subcutaneous adipose tissue. There was also great hypertrophy of connective tissue between the muscular fibres, which were frequently much reduced in diameter, although they were not otherwise much altered. Duchenne and Ordoñez found the striæ on the fibres very much finer than usual, and semi-transparent. The same appearance, together with an increase of connective tissue, and large collections of fat-cells, were also observed in one case by L. Clarke. The disease is regarded by some as closely related to progressive muscular atrophy, i.e. as only a modification of the latter. (Eulenburg *l. c.*)

Treatment.—During its first stage the disease is sometimes curable. Duchenne has recorded two such cases.² But in the second stage scarcely any hopes of recovery can be entertained. The treatment consists chiefly of local Faradization and shampooing.

Ossification of muscle is occasionally met with, leading to the most remarkable deformity. The deposit is composed of true bone with cancelli, compact shell, periosteum, and cartilage, displaying also under the microscope all the signs of true bone. Ossific growths may take place over a large extent of the voluntary muscles, or may be limited to one or two points. In the Museum of the College of Surgeons is the skeleton of a man in whom nearly all the muscles of the back had become ossified, masses of bone occupying the places of the latissimus dorsi, spinalis, and rhomboid muscles, forming large bony sheets on the back and sides, while large stalactical growths spring from the pelvis, ribs, and scapulae. The following case is valuable from the circumstance of its progress having been watched from its commencement up to its very advanced stage in 1862, when the account was published.

G. Brown, aged twenty-two, was originally admitted into St. George's Hospital under the care of Mr. Caesar Hawkins in August 1843³ with swellings in the dorsal and lumbar regions, some of them apparently bony. Their appearance was accompanied with severe rheumatic pains. All these disappeared under treatment. They reappeared, however, and then one was removed from between the trapezius and rhomboid muscles; it was intimately connected to both, fibres from each being inserted into it, one end of it was fixed to the spines of the sixth and seventh dorsal vertebrae, the other was smooth, playing on the end of the scapula. After this, for four years, fresh tumours were observed to form in different muscles of the trunk and neck, being at first soft, growing rapidly, then becoming hard, and, after a time, either disappearing altogether under treatment, or leaving a bony deposit behind. This new bone extended slowly towards either extremity of the muscle in ridges corresponding to its fibres. He was now lost sight of, but in June 1859 again presented himself at St. George's Hospital, with extensive ossification of the muscles, together with several exostoses both on the spine and ribs. The greater part of the latissimus dorsi on either side, especially at the free edges, was ossified; large masses of bone filled up the hollows on either side of the vertebral spines from the sacrum to the occiput, soldering all the bones together into an inflexible column. The ribs were likewise immovable, partly from being ankylosed to the spine, and partly by the ossification of the muscles connecting them with the scapula and spine; so that respiration was entirely performed by the diaphragm. The trapezius, and, apparently, the deep muscles at the side of the neck, contained large deposits of bone; both scapulae were immovably fixed to the ribs, principally by the ossification of the serratus magnus and rhomboid muscles. In front, both the great pectoral muscles, from their origins to their insertions, were almost entirely ossified, presenting ridges taking the course of the fibres, and forming large masses at the folds of the axilla. The sterno-hyoid and sterno-thyroid muscles were much ossified; and these, together with the recent appearance of a considerable swelling below the chin, had been accompanied with so much difficulty in deglutition as to alarm him; he therefore came to the hospital to see Mr. Caesar Hawkins, under whose care he had before been. The fulness in the upper part of the throat was not hard, but very tender; it yielded to a second application of a blister in a few weeks, so that the genio- and mylo-hyoid muscles could be distinctly felt almost entirely ossified. Preparations from this case are in the Museum of St. George's Hospital.

The cause of this osseous growth in muscles is not always easily explained. A tendency to increased bony deposit is not very uncommon, and shows itself in

¹ *Pseudo-Hypertrophic Muscular Paralysis*. (Churchill, London, 1879.)

² *De la Paralyse musculaire pseudo-hypertrophique*, Paris, 1868; and *Archives gén. de Méd.* Janvier et seq. 1868.

³ *Med. Gaz.* vol. xxxiv. 1844, p. 278.

exostosis and extension of bony growth into the tendons inserted into the bones; but in ossific growth in muscle it is a distinct formation, and in no way, at first, connected with exostosis. That it is of inflammatory origin, the pain and swelling, and also the effects of remedies, would appear however to indicate clinically, as well as the observation of Munchmeyer (*vide* Rindfleisch¹), who showed clearly that we have here to do with an actual ossification of interstitial exudation, or 'Myositis ossificans multiplex progressiva.' The disease is also in many cases evidently directly due to chronic irritation from recurring injury, acting on those with a peculiar predisposition. Thus it was common among the Prussian soldiers of former days when a drill regulation required the musket to be brought up against the deltoid repeatedly with a sharp rap. The consequence of this was in many cases the formation of what was known as the 'drill bone.' This consisted of a somewhat triangular plate of bone, springing from the insertion of the deltoid and running upwards in the muscle for from three to five inches. It was usually one to two inches broad, and had a circumference of four to five inches. Abernethy² also mentions the case of a lad in whom an exostosis or bony growth in a muscle invariably followed a blow on the part. Again, myositis ossificans is sometimes met with at the origin of the adductor muscles of the thigh, starting from the pubic or ischial ramus as a consequence of the irritation and pressure on the part in those who ride much.

As regards the treatment, no local measures answered in the above case so well as blisters, under which, with the exhibition of colchicum internally, considerable diminution of the swellings and relief of the pain took place. The swellings completely disappeared after a course of the iodide of potassium, at first five, and then seven, grains thrice a day in sarsaparilla, but they returned again shortly after, while the patient was still taking the medicine. On the reappearance of the disease, mercury was given, two grains of calomel and a quarter of a grain of opium twice daily, which at the end of three weeks produced sore mouth; again, all the swellings were nearly removed, at first rapidly, then slowly; but a large mass of bone between the scapula and spine was removed, as stated, by operation. After this, from hæmorrhage and other causes, his health failed, and he was much reduced, and specifics were laid aside for some time. Numerous fresh tumours having, however, formed, he, in a few months, began the phosphoric acid, first in half-drachm, and afterwards in drachm, doses, three times daily, which he continued from April 6 to May 21. The swellings greatly diminished under this treatment, and with the repeated application of blisters their recurrence seems to have been arrested. Thus the remedies appear to have been chosen with a view to the inflammatory nature of the complaint, and to have been most efficacious; yet so strong was the tendency to relapse, that the swellings formed again and again, even under the treatment that had caused them to disappear. They were, however, finally arrested, the blisters having been most conducive to that end.

TUMOURS IN MUSCLES.

Tumours of various kinds are often found in muscles either as primary or secondary growths. The primary new growths here are, however, few. They consist in the fibromata, enchondromata, or fibro-enchondromata, the myxomata, or lipomata. Most usually the new growths occur in muscle proper as extensions from neighbouring parts, or as secondary deposits. Primary sarcomata are rare here. When neoplasms are present, they are developed from the young connective tissue between the muscular bundles. In their growth they lead to degeneration of the latter by pressure which may be simple, or granular, or fatty.

Primary carcinoma of muscles is unknown, but secondary deposits from both scirrhus and encephaloid are frequent. The same effect is produced upon the muscle bundles here as above.

Epithelioma is only found in muscles as an extension from neighbouring mucous membranes. It presents no peculiar characters here.

¹ *Path. Histology* (American translation), p. 676.

² *Surg. Lect.* iii. 189; *Lancet*, April 1826.

Gummata have already been described as occurring here, and tubercular deposits are likewise found (*vide* DISEASES OF TONGUE).

Vascular tumours or angiomas are not infrequent in muscles. Here they occupy the interstitial connective tissue, and may attain some size. They must not be confounded with varices. Extravasations of blood occurring from injury or in the course of an attack of scurvy may also give rise to fibrinous knots in muscle which must not be mistaken for new growths.

Cysts of various kinds are occasionally found in muscles. Some of these cysts contain hydatids. Such is the *trichina spiralis*, a bisexual and minute nematode worm which is reproduced viviparously by the female parent. The female trichina is about one-third longer than the male, and in the mature state contains in its uterus a variable number of ova, as well as free embryos in different stages of development. When the flesh of an animal containing spiral trichinae is eaten by another, the contents of the small intestines are found, after about twenty-four hours, to contain a multitude of these worms, which lie imbedded in the mucus or in the chyme. Soon after the embryos are born, they begin to migrate from the intestines in search of muscular tissue, upon which they feed and develop. Concerning the manner in which migration is effected, there is some difference of opinion. Most observers believe that the young trichinae pierce the walls of the intestines and other parts until they reach the muscles; while other observers, with Dr. Thudichum,¹ contend that, after penetrating the mucous membrane of the intestines, they enter the blood-vessels and lymphatics, pierce the lymphatic glands, reach the heart with the venous blood, traverse the lungs, and are then distributed, by the arterial circulation, to all parts of the body. However, having reached the muscles, there they feed, and grow, and ultimately become encapsuled. Leuckart maintains that the young trichina always penetrates the sarcolemma, while other observers assert that it lives and grows either inside or outside that sheath. However this may be, so long as the worm remains outside, the muscular fibre is not permanently damaged, although it becomes somewhat granular, and loses the distinctness of its transverse striation. But if the parasite pierces the sarcolemma, the fibre is permanently destroyed; the sarcomerous elements are disarranged, broken up, and transformed into granular masses, which constitute the food of the invader. As the trichina reaches its full growth and becomes fixed to one spot, the interstitial connective tissue and the sarcolemma around it, being irritated and inflamed, throw out an exudation, while the nuclei of both enlarge, divide, and rapidly multiply. The exudation, which appears to consist of fluid fibrine, soon after solidifies and forms a capsule in which the worm coils itself up. At the end of some weeks after infection, fine dark granules of carbonate of lime and magnesia are deposited in variable numbers within the capsule, and render it more or less opaque.

In man, trichiniasis is produced by the ingestion of imperfectly-cooked flesh of animals infested with trichinae—particularly pigs.

The pathognomonic symptoms of trichiniasis are the following:—

Sudden swelling of the face, particularly the eyelids, after the patient has for some days felt prostrate and lost his appetite; fever, with quick pulse and copious perspirations, which have sometimes an offensive odour; painfulness and immobility of arms and legs; the muscles are swollen and contracted, and give great pain when set in motion or touched; the limbs are semiflexed; gastro-intestinal catarrh, with red and somewhat dry tongue; when the swelling of the face has subsided, the feet, legs, and thighs become oedematous, and soon after anasarca over the trunk ensues. There is no other disease in which this particular combination of symptoms occurs.

Cysts containing a black, tenacious matter are occasionally found in muscles; they probably are of the nature of hematoma occurring in other parts of the body, being merely unabsorbed extravasated blood, which has become darkened and inspissated by time. Warren describes a singular tumour somewhat of this nature. This was about the size of an egg, and was removed from the substance of the rectus

¹ See Thudichum, *Seventh Report of the Medical Officer of the Privy Council*, 1864. Also Althaus, *Med. Times and Gaz.*, 1864.

femoris muscle of a woman; it was said to be of only five or six months' growth; it consisted of a hard dark-coloured muscular substance, in the centre of which was a bony shell an inch in diameter, containing a dark-coloured fluid, which had deposited a black crust on the bony cysts.

AFFECTIONS OF TENDONS, THEIR SHEATHS AND BURSÆ.

Injuries of tendons.—It has been already observed that tendons are ruptured by the action of their muscles more readily than the muscles themselves; they may also be torn by direct force, as in dislocation, and they are often divided partially or entirely in wounds, and by subcutaneous sections. When a tendon is ruptured, or, what is nearly the same thing, divided by subcutaneous operation, the part which is attached to the muscle is drawn away from the opposite end for about an inch; this latter is but slightly retracted by the action of its antagonists. Blood is poured out between the ends, but much less than in rupture of muscles. The pain is said to be not very great; a considerable shock, however, is felt, as from a blow received on the part, accompanied by cramp of the muscle, and a perfect inability to use the limb; and in rupture of the tendo Achillis a feeling is described as if the heel were sinking into a hole in the floor. The tendons most frequently ruptured are the tendo Achillis, and the tendons of the rectus femoris, and the triceps humeri. If the separation of the ends be not too great either in rupture or subcutaneous division, they unite with much readiness, the new material soon acquiring great firmness. So rapidly is the process of repair carried on, especially in the early stage, that, according to Mr. Paget, in his sixth lecture at the College of Surgeons, a specimen six days after division (being the fourth occupied in the organism of the new structure) could bear the weight of twenty-five pounds; in another case the new material at the end of twenty-one days bore a weight of fifty-six pounds. The process of repair is briefly this. For the first forty-eight hours plastic matter is poured out, the tissues around the divided ends encasing the latter and the effused blood. In five or six days, this material can be seen to be nucleated, and to be assuming a definite cord-like form. The cut ends of the tendon swell at the same time, become softened and vascular, until their tissue comes to resemble the plastic matter lying between them. The vessels of both now intercommunicate, and they are thus thoroughly fused into one. The plastic matter now becomes filamentous, its cells lengthening out into threads, thus using up all their protoplasm and leaving only the nuclei behind. Then the vascularity decreases in both the new material and in the softened ends of the tendon; both become firmer, until about the tenth day they are pale and firm. In about three weeks the process is completed, and a strong cord of fibrous tissue is formed, in all points a complete tendon. Should the interval between the two ends of a divided tendon be great, a very imperfect bond of union will be established between them, as the end will become attached to the neighbouring tissues, and either a partial or entire loss of the use of the muscle will result. Where the integuments and surrounding parts are included in a division of a tendon, there is, as in muscle, a much greater retraction than where these parts remain entire; added to which, the material for the repair of the tendon being here common to all the other tissues included in the wound, they all become fused into a common cicatrix, so that under the most favourable circumstances a very imperfect cord and limited use of the muscle remain.

The treatment of ruptured tendon consists, as in rupture of muscle, in approximating the divided ends as far as possible, and retaining them in that position until firm union is established. Close adaptation cannot be hoped for in all cases, but still a perfect union with recovery of the action of the muscle usually takes place. Whenever practicable, an attempt should be made to defend the wound from the contact of all impurities, and to render it aseptic if an open one. If this can be done, the divided ends of the tendon may be brought together with sutures, and a better result obtained than otherwise, unless suppuration subsequently take place. The severed ends are also brought closer and closer towards one another by the contraction of the

material as it becomes perfected, and the remaining deficiency is fully compensated for by the accommodating nature of the muscle. If the tendon of the triceps be torn, all that is required is a bandage from above downward, with a splint in front of the arm to keep it extended : and as the union of tendon is rapid, passive motion should be employed early. In rupture of the tendon of the quadriceps extensor cruris, the same treatment nearly may be adopted as for a fractured patella. Where the tendo Achillis is torn across, the treatment consists in keeping the foot extended on the leg, and the leg bent on the thigh ; a position favourable to the relaxation of the gastrocnemii muscles. For this purpose a belt is placed round the thigh a little above the knee, the back of which is attached to the heel of a slipper by means of a belt or bar. Before applying the instrument, the calf of the leg should be bandaged from above downward, care being taken not to approach too near the seat of rupture, for a great displacement and permanent defect would result from the ends of the tendon being pressed towards the bones of the leg, somewhat the same inconvenience may occur from a too considerable or a too long-continued tilting up the heel. De-sault, to avoid the displacement of the tendon by his bandage, which, like Petit's, extended over the whole limb, recommends compresses at the sides of the tendon. John Hunter, who himself had a rupture of the tendo Achillis, recommends that, as so little inconvenience attends a small separation of the tendon, compared to the great trouble and difficulties attending the treatment by bandages and straps, the parts should be allowed to remain in their natural position. He is, however, disposed to adopt a middle line of practice, and suggests that the heel should be elevated during walking, by raising the heel of the shoe ; that a bandage should be kept steadily applied to the calf of the leg, to guard against involuntary actions of the muscles ; and that at night the usual slipper and strap might be applied. There would be so little objection, however, in most cases, to a patient with such an injury remaining in bed for the few weeks necessary for repair, that probably this would be the best line to take, keeping the leg flexed over the thigh, and the heel drawn up with the slipper. Bandages are not well borne, rest, therefore, with position, must be trusted to for the cure.

Inflammation of tendons.—Tendons being formed of highly developed fibrous tissue but little vascular, and having no active functions in the economy, are almost exempted from primary inflammation. As the result of injury to their fibres from stretching or tearing, they may primarily become the seat of plastic changes to a greater or less extent, which differ in degree only from what has been described in speaking of ruptured tendons (p. 171). Secondly, tendons may become inflamed as a consequence of inflammation of the synovial lining of their sheaths, as we shall see in speaking of affections of the latter and the bursa.

Tumours of tendons.—For the same reason that tendons are rarely affected with primary inflammation, they are rarely the seat of primary new growths. And not only this, but they resist for a long time the invasion of those neoplasms which attack them from without. The only indigenous neoplasms met with in them commonly are enchondromata, which may here attain some size. Some of the bursal tumours closely related to the tendons may appear to spring from them, but careful dissection will show their independence. Small nodules of bone are also found here generally near the insertion of the tendons, and are apparently due to ossification of small enchondromata, or to inflammation (*vide* p. 169). Carcinomatous and sarcomatous growths are almost unknown.

Gummata are not common in tendons, but are met with occasionally. They are deposited here between the fasciculi as in the case of muscle. When present thus, they indicate an advanced stage of the constitutional disease, and a condition generally which resists treatment. The latter will be the same as that for the other advanced tertiary lesions of syphilis, and will require to be carefully conducted.

Synovial sheaths.—Besides those of the joints, there are two kinds of synovial sacs having a close relation to tendons which require consideration—those investing tendons, and those situated in the subcutaneous cellular tissue. These cavities, lined like the joints, are liable to the same inflammatory affections, and we find in them

consequently both acute, sub-acute, and chronic teno-synovitis, or bursitis, as it is often called in the last case, produced either by simple causes such as blows, over-exertion, &c., acting from without, or by constitutional causes acting from within (*vide DISEASES OF JOINTS*).

Simple acute teno-synovitis is not often met with, unless after great violence to a limb, when the greater injuries almost sure to be present besides withdraw our attention from the lesser. The sub-acute form is not infrequently met with as the result of over-exertion, either of the hand or foot, most commonly in the extensor sheaths. The patient notices stiffness of the part, with local tenderness and pain soon after, which on examination are found to be limited to the course of one or other of the sheaths. There will also be felt a slight crackling or creaking in the latter when the part is moved. The suffering is not great, but much local weakness is complained of as a consequence of the affection. The treatment will consist in rest to the part, with application of a few leeches or hot belladonna fomentations at first. Later on when all heat has disappeared, and only stiffness and weakness remain, the part may be painted with iodine tincture, and strapped carefully with strips of adhesive plaster overlapping in the usual way, so as to give support to the sheath. Passive motion should also be had recourse to early, but not active until the part is almost painless. Later on an elastic covering will be desirable, while the patient is exerting the member.

Simple chronic teno-synovitis is also occasionally present as the result of the latter, or from chronic irritation. Here the more active changes once present have gone, leaving some effusion and thickening in the synovial sac, as a consequence of which weakness is felt and rubbing or creaking when the tendon is moved. Blisters and other counter-irritants are called for here, and may be alternated with firm strapping for the part. Under this treatment all evidence of inflammation soon disappears, except a little roughness in the movement of the tendon, which takes longer to subside.

Ganglion.—It is as a consequence probably of this chronic simple teno-synovitis, combined with repeated over-strain of the weakened sheaths, that those fluid swellings about joints to which the name ganglia or bursal tumours is often applied, are produced. These are most frequently met with about the wrists or ankles either on the anterior or posterior aspect. Those of the hands, which may be taken as good examples, usually occur among people whose occupation leads them to make sudden and violent exertions of an irregular kind, such as wringing among laundresses, &c., at the same time that the part is exposed to extreme variations of temperature, heating and chilling, *e.g.* in laundry work. Here it would appear as though we had not only a tendency to chronic irritation of the synovial linings of the sheaths of the tendons, but actually a weakening of the fibres of the latter by distension and over-strain at the same time. This leads in simple cases to a gradual dilatation of the sheath, and its synovial sac, until a fluctuating tumour is formed, of greater or less dimensions. For instance, such a process may lead on the front of the wrist to distension of the synovial sac of the flexor tendons, and stretching of their sheath, until a fluid tumour may be felt, not only in the palm of the hand, but also above the annular ligament of the wrist. The same may be met with in the sheaths of the extensors of the thumb, behind and in front of the external malleolus, and about the hamstring tendons.

Besides the presence of the swelling in such cases, patients will complain of great weakness and a little pain on using the affected sheaths. This weakness is easily explained by the fact that the tendon is no longer tightly confined in its groove, and acts therefore at a disadvantage. Otherwise there is little abnormal about the part, and the lining and its secretion are almost as in health. It is not hot, unless in addition an attack of inflammation supervene from any cause. This is not so very uncommon, the part being once weakened. The result then will be heat, tenderness, and even redness, over the swelling, which now appears fuller than usual. In this state we find the addition of fibrinous shreds to the thick synovium, and some turbidity of the latter. Such attacks as this not infrequently give rise to the production of a considerable quantity of plastic or fibrinous material within the synovial sac. This

may either cover the walls in irregular layers, or during the movements of the parts become rolled into small flattened oval pellets like melon seeds, which can be felt through the walls of the sac as they slip about like a bag-full of peas, producing a peculiar crepitation almost unmistakable. When such a sac, then, is opened we often find such plastic matter in abundance in both these forms. These loose bodies are probably also formed occasionally by small pendulous fringes of synovial membrane thickened by plastic deposit being detached during movement of the part.

Such ganglia, if extensive, are by no means easy to treat effectively. Rest and repeated counter-irritation by blisters and iodine ointment should first be tried, in the hope that the effusion may be absorbed, and the sheath shrink back to its normal condition. In many cases it will do this, but only to return to its former state on exerting the part again. Repeated tapping, carefully conducted with hollow needle or tenotome, should then be tried, the wound each time being small and guarded against contamination. In those cases, too, where there are fibrinous deposits in the sac, the sheath cannot of ~~of~~ ~~the~~ resume its original condition. Here, then, and especially if the part be inclined to attacks of inflammation, an incision is called for to evacuate all the solid contents of the sac, whatever they may be. This should be done with the strictest antiseptic precautions. The opening being made over the thinnest part of the swelling, the fibrinous bodies should be squeezed out completely, or any adherent plastic material scraped off the walls of the sac with a Volkmann's spoon. A drain tube or wisp of horse-hair should then be laid in the opening and retained there till the sac has contracted completely. This will generally require a considerable time, and will not always lead to a complete restoration of power to the part at once. But with passive motion, counter-irritants, and supports, much improvement will eventually take place. Sometimes it may be necessary to make two openings in such a sac in order, in the first place, to evacuate it completely, and in the next to drain it thoroughly until contracted.

Compound ganglion.—Another kind of 'ganglion,' often called compound, is frequently found either distinct from, or associated with, the condition just noticed. Here, during some extraordinary exertion, the weakened sheath gives way at one spot or another; and a gradual protrusion of the synovial tissues takes place through the rent. This will give rise to a tumour of larger or smaller size, usually much more tense than the first variety, but capable of being emptied as a rule by pressure into the sheath. Its growth is slow, and it is usually only troublesome from the weakness associated with it, and from the chronic irritation and simple distension of the sheath. Occasionally, if the original rent in the latter be small, it may sooner or later close again, and then we find a small elastic tumour incapable of being emptied into the sheath, by any pressure, but, from its history, position, &c., manifestly of the same nature as that last described. A puncture with a tenotome will usually decide the question, and give exit to some transparent and very thick synovial jelly.

Both these last varieties of ganglia, which are usually smaller than the first produced by simple distension of synovial sac and sheath, are usually quite amenable to treatment. They may be sometimes ruptured by simple pressure, when their contents, effused under the skin, are rapidly absorbed without inflammation. Or, if this do not succeed, a tenotome may be thrust into them, and their fluid be allowed to run out either externally or under the skin. If this be done with rigid cleanliness, no trouble will follow. When the sac is thus collapsed, it should be supported by firm pressure, and should be acted on with counter-irritants, otherwise it is apt to fill again. Two or three tapplings, followed up as indicated, will generally suffice to cure the condition permanently as regards the swelling; but weakness often lasts for a considerable time.

With regard to teno-synovitis and bursitis, produced by constitutional causes, they are not unfrequently met with. Thus, in any of the pyæmic conditions, in gout or rheumatism, &c., synovitis within and swelling of the synovial sheaths or bursæ are common both in the acute, sub-acute, and chronic forms. The ætiology of these conditions being the same as that of the analogous synovial affections of joints, the reader is referred to the article on 'DISEASES OF THE JOINTS.' The

general treatment, too, discussed there will cover these conditions of the sheaths and bursæ, so that nothing further need be said of them here. This specific synovitis of extra-articular synovial sacs should not be forgotten, as in the acute form it will give rise to acute effusion or abscess in parts, out of the way of the ordinary exciting causes of simple synovitis.

Acute teno-synovitis, as a consequence of the direct entrance of septic matter into the synovial sac, is a common affection. It is found frequently in that class of diseases under the old name of 'whitlow.' In that form described as *paronychia tendinosa*,¹ or *thecal abscess*, the inflammation is most dangerous. Here the most destructive changes are often brought about in one or more fingers or in the hand and arm to which the disease has extended along the synovial tracts. In many cases, the joints and bones become extensively implicated. It arises from the same causes as the other forms of paronychia, i.e. slight wounds or pricks with inoculation of some septic matter, often, however, without any distinct history of this, especially when the state of the health is bad. It begins with severe throbbing pain on the palmar surface of the finger, which extends along the arm, often as far as the shoulder; it is accompanied by redness and swelling, with great hardness and tension; if not checked, the inflammation proceeds quickly along the front of the finger, and is soon followed by suppuration in the sheath; this at first is in small quantity, and, in consequence of the great hardness and swelling of the part, cannot be detected by the touch; if no relief be afforded, the suppuration quickly proceeds along the sheath, the inflammation and pain are aggravated by the density and unyielding nature of the parts, and are accompanied by much constitutional disturbance; abscesses burst externally from time to time as the disease extends upwards, from which fungous granulations spring, the tendon in a sloughy state lying at the bottom. With proper treatment, and in a favourable state of the general health, the progress may be arrested with a greater or less amount of destruction of the parts attacked, and a proportionate deformity. In certain unhealthy states of the system, however, in which the diffuse or erysipelatous form of inflammation prevails, the inflammation and suppuration extend into the palm of the hand behind the palmar fascia, and to the rest of the fingers. The whole hand now presents a highly inflamed appearance, of an erysipelatous nature, with great swelling and tension; nor does the mischief end here, but, passing under the transverse ligament of the wrist, ascends into the forearm, forming large diffuse abscesses amongst its tendons and muscles; and in the worst cases, not only the joints of the finger, but those of the carpus and wrist, are destroyed, and the bones denuded and necrosed. The health during this time suffers severely from irritative fever, with gradual prostration of the bodily powers.

Treatment.—In the very early stage the inflammation may often be arrested by leeches, followed by hot belladonna fomentations to soften and relax the hard and unyielding tissues. The hand should be elevated, and an active purgative, with other antiphlogistic measures, prescribed; if relief do not soon follow, but, on the contrary, the continuance of pain and throbbing, with increased hardness, indicate the extension of the inflammation, if not the formation of pus, no further time must be lost; a free incision must be made along the centre of the finger, and though there may be but very little or no pus in the sheath, yet the division of the tensely strangulated structure, and the escape of blood and serum, afford the greatest relief. By these means all mischief may be arrested, and the finger perfectly restored; especially if the incisions have been made with all antiseptic precautions. On the other hand, the inflammation may proceed along the sheath in spite of the most ready treatment; suppuration may have extended under the palmar fascia; further incisions must then be made; and it will now be found proper to support the powers of the system by a generous diet, stimuli, and tonics. In these cases the tendon will slough, and one or more of the joints will be ankylosed, with such disfiguration as may at a future time require amputation; for a stiff and distorted finger, in almost any condition of life, is very inconvenient as well as unsightly. In the more chronic states, where, notwithstanding free openings having been made in the palm, abscesses

¹ Abernethy, *loc. cit.*

burrow about the hand, the best results follow from constant immersion of the part in hot water, to which some non-irritating antiseptic has been added, alternating with hot boracic fomentations, the powers being supported with tonics, good diet, and stimuli. Where the suppuration extends to the arm, the case is more serious; and if, from the state of the constitution before alluded to, it proceeds to the indiscriminate destruction of the joints, nothing but amputation remains, and even that may not save life.

Diseases of Bursæ.—Turning to the affections of the bursæ proper, we find them analogous in almost all respects to those of the synovial sheaths of tendons. We encounter in them both simple and specific synovitis, whether acute, subacute, or chronic, and producing very similar, if not identical, grosser effects. Thus we have effusion in every degree, from a trifling excess of synovium to the production of pus; or, in the chronic form, from slight thickening, with roughening of the internal bursal surface, to the deposit of vast masses of fibrinous material within the sac, either covering its walls, or rolled and worked by movement into those melon-seed bodies already alluded to (p. 174). But, although almost any of the bursæ mucosæ of the body may be affected, there are a few which so frequently come under our notice as to call for a few moments of special consideration. The bursa patellæ is one of those, its simple affections being usually grouped under the name of ‘housemaid’s knee,’ so frequent is it in this class. Here it is usually brought on by kneeling, and may be, as already said, acute, sub-acute, or chronic. In the first, early antiseptic evacuation of the effusion is the best practice, if there be any suspicion of its being purulent, lest, as most surgeons must have seen, the collection burst subcutaneously and produce extensive abscess around and about the knee, threatening the joint. In the less severe forms rest, with antiphlogistics, as already indicated, will usually suffice to relieve the patient. In the chronic form, where there is much fibrinous deposit in the joint, and the part is painful, it is usually the best practice to dissect out the whole sac bodily, with all precautions as to aseptic wounds. This may be easily done by a single vertical incision, the hard round body coming away without difficulty, and leaving a clean healthy cavity behind to unite by first intention. The objection to leaving these greatly thickened bursæ patellæ alone is that the constant pressure of the hard mass under the skin, with the rubbing and pressure to which the latter is subject, will in many cases lead to ulceration, leading either into or from the rugged cavity within the fibrinous mass. If this take place, unhealthy sinuses may exist for long periods, discharging curdy, broken-down fibrin; or the inflammation may spread from the now open sac to the tissues around, giving rise to much trouble and some danger.

In those cases where there is a simple effusion of serous synovium into the sac which resists the action of counter-irritants, the treatment will consist in simple tapping with a needle or tenotome, with subsequent strapping of the part. If after this there remain much induration of the walls, with a tendency to refill, a free opening and aseptic drainage, as described for the ganglia, may be tried before proceeding to enucleation of the whole sac.

What has just been said of the bursa patellæ applies equally to the affections of that over the olecranon, which are also grouped commonly under the name of ‘miner’s elbow,’ from the frequency of these conditions among those who work long on their hands and knees. Here the fibrinous exudation is not so likely to be troublesome; but in other respects the conditions and their treatment will be the same.

Again, the bursa between the ligamentum patellæ and tibia sometimes enlarges and forms a tumour, which, by filling up the depression on each side of the ligament, presents the appearance at first of synovitis of the knee-joint; but the absence of swelling above and around the patella renders the diagnosis easy. Distension of the bursa above the knee usually accompanies synovitis, because this bursa almost always communicates with the joint; this, however, is not always the case, and large bursal tumours under the vasti have been seen, the joint being quite healthy. One of the bursæ of the hamstring muscles (usually that of the biceps) occasionally enlarges, and appears in the ham as a tumour, sometimes pulsating, often of considerable size; it is, however, too little like an aneurism to be mistaken for one by a careful observer. The

same may be said of the bursa of the sub-capularis, and other sacs about the shoulder-joint, which sometimes form tumours in the axilla, occasionally pulsating from their vicinity to the artery. The bursa between the psoas and iliacus internus and the capsule of the hip-joint sometimes forms a tumour, which from its situation may be mistaken either for an inguinal aneurism or for a psoas abscess; the extrinsic character of the pulsation and the absence of all other aneurismal symptoms in the one case, and the want of spinal symptoms and of fluctuation above Poupart's ligament in the other, assist in forming a right diagnosis. This bursa occasionally communicates with the synovial membrane of the joint, and when inflammation occurs in the former, the latter will most likely be involved in it, and serious mischief may follow. The bursa between the gluteus maximus and tuber ischii, that between the tendon of the gluteus medius and the trochanter, and that between the latissimus dorsi and the angle of the scapula, from their exposure to pressure and other sources of irritation and inflammation, are not only liable to inflame, but even to suppurate. When, from frequently recurring pressure in sitting, the already enlarged ischio-gluteal bursa inflames and suppurates, it increases in size, becomes painful, and renders sitting on the part impossible, and even motion distressing; lying deep under the mass of muscle, its fluctuation is obscure, and the suppuration is usually slow in coming to the surface, and after it is evacuated, it often leaves a sinus obstinate and slow to heal, from its depth and the movements of the muscle. The same may be said in most respects of the bursa over the trochanter. That at the angle of the scapula often acquires a great size, and when it suppurates, much constitutional disturbance is often set up. Too much caution cannot be taken in opening these bursa, whether in their simply enlarged state or in the suppurating stage, as an alarming and even fatal train of symptoms sometimes follows the operation.¹

DISEASES AND INJURIES OF NERVES.

PART I.

NERVE-LESIONS AND THEIR MORE IMMEDIATE EFFECTS.

DISEASES OF NERVES.

NERVES are subject to as many disorders and injuries as most of the other tissues of the body. They are liable to inflammation, suppuration, ulceration, and gangrene; to atrophy and enlargement; to softening and induration; to the formation of cysts, fibrous or neuromatous tumours, and cancerous growths along their course; to compression or stretching; to contusions, lacerations, punctures, and partial or complete division.

Inflammation of Nerves (Neuritis).

Neuritis is not as common an affection as supposed by Remak and Benedikt, who believe that it exists in most cases of neuralgia and other neuroses. In animals, as shown by Vulpian and Weir Mitchell, it is extremely difficult to produce an inflammation of nerves, and in man it is not rare to find nerves surrounded by the pus of a large abscess without any inflammation except of their outer sheath. Still, a prick, a contusion, a prolonged pressure, an inflammation of neighbouring tissues, are well-known causes of neuritis. General causes also can produce neuritis, as seen in typhoid and eruptive fevers, alcoholism, syphilis, leprosy, poisoning by lead or the oxide of carbon, diphtheria (Buhl). Diseases of the brain will also bring on neuritis, as shown by L. Türck, Vulpian, Charcot, Bouchard, Westphal and others. Optic neuritis is known to be often due to cerebral tumours (J. Hughlings Jackson, Galezowsky). Localised spinal meningitis may also be a cause of neuritis, as one of the writers (Dr. B.-S.) has seen in two cases. The only known cause of neuritis outside of cases of diseases or injuries of the nervous system, or of an alteration of the blood, is an influence exerted by cold or dampness.

Pathological anatomy of neuritis.—In its *acute* form this affection is characterised by redness, swelling and serous exudation of the cellular tissue of nerves. Intense congestion exists both of the outer sheath and that of the fascicles of the inflamed nerve, with or without punctiform ecchymoses. When the inflammation is very intense the nerve is softened, disaggregated, and the altered nerve-tubes form a brownish, soft mass. The morbid process may be more advanced, so that only fragments of the nerve-tubes can be found, and sometimes degenerated into fat. However, in ordinary acute neuritis, especially when due to inflammation of neighbouring tissues, nerve-fibres may remain perfectly normal, as shown by Cornil and Ranvier, owing to the protection of the cellular sheaths of the nerve, keeping pus outside of these nerve-elements. Such is frequently the case in secondary peri or interstitial neuritis. Charcot, Pierret and Joffroy have described a very rare form of neuritis (*parenchymatous*), characterised by the moniliform appearance of nerve-tubes, the proliferation of the cells belonging to the segments of these tubes, and the disappearance of the cylinder axis. In its *chronic* form neuritis is characterised by the greyish, bluish, or almost violet colour of the affected nerve, which is swollen and offers nodosities. The neurilemma adheres to surrounding tissues. If the inflammation is limited to that

membrane (*perineuritis*), the nerve-fibres remain generally quite normal, but if it extends to the interstitial sheaths, there is pressure on the nerve-tubes and consequently atrophic degeneration.

Acute neuritis is often preceded by the usual prodromata of inflammation. Its characteristic symptoms consist of a tearing, darting, or lancinating pain chiefly along the course of a nerve-trunk or its branches, but also along the neighbouring nerves, attended with a sensation of tingling, formication, or numbness. The pain never becomes suddenly severe or ceases suddenly, or intermits, as in neuralgia; for although it frequently remits or abates, it is a continuous pain which gradually increases in intensity and gradually subsides. It is always aggravated by pressure on the inflamed portion of the nerve, by contraction of the muscles to which it distributes branches, or even by the slightest touch along its peripheral course; while, on the other hand, it is relieved by firm pressure above the seat of the inflammation. If the affected nerve is superficial, its swelling, hardness and nodosity are easily recognised, and these altered parts are found to be the principal seats of pain. A period of general hyperæsthesia may exist in the beginning, but is usually soon replaced by anaesthesia in almost all the parts receiving nerve-fibres from the affected nerve, the loss of feeling co-existing then with the radiating pains. This association of pain and anaesthesia is found in ordinary acute neuritis, in *ophthalmic zona* (Hylbrand), and in *Lepra anæsthetica* (Rendu), affections in which a real acute neuritis exists. Sometimes there is a change in the skin at or near the principal seat of inflammation of the nerve. There is a red swelling, which may be mistaken for a boil, but, as shown by Ramiak, it changes rapidly in size and colour, so that it cannot long be a cause of mistake. The local motor symptoms are variable: - there may be trembling, twitching, cramps, choreiform or tetaniform contractions; there may be, on the contrary, a more or less complete local paralysis. The vaso motor nervous system is often disturbed, so that there is a vascular contracture or dilatation. In a case now under the care of one of the writers (Dr. Brown-Séquard) there is vascular contraction with great coldness in one part, while there is dilatation with increase of temperature in another. Friedreich, Klemm, Vulpian and Erb have ascertained that acute neuritis often causes rapid muscular atrophy. One of the writers (Dr. B.-S.) has seen a marked atrophy of the muscles of the thigh and leg, occurring in two days in a dog. That atrophy is produced by a direct morbid influence exerted by the irritated nerve on the nutrition of muscles, as maintained by one of the writers, but Vulpian believes that it is due to a cessation of the proper trophic influence of the spinal cord on muscles. Faradisation soon ceases to act on muscles becoming atrophied. But in the beginning of acute neuritis, galvanism may act with great power (Erb). The pulse is frequently strong and quick, the temperature of the skin over the inflamed part is much increased, and there is generally a variable degree of sympathetic fever, in proportion to the size of the affected nerve and the intensity of the inflammation. A great variety of local alterations of nutrition have been noticed in acute neuritis. We will only point out the existence of the following: bullæ or vesicular eruptions (Rouget, Charcot, Sir James Paget, Earl, Raynaud, Mougeot, Coulyba, Weir Mitchell), sometimes pemphigus (Charcot), eczema (Mitchell), ulceration (Paget, Hutchinson, Brown-Séquard), glossy skin (Paget, Mitchell), fall of hair, nails clubbed, scaly, cracked and fragile (Mitchell and others), ichthyosis (Brown-Séquard), atrophy or hypertrophy of skin (Charcot, Mitchell, Brown-Séquard). The remote and the reflex symptoms will be described in the second part of this article.

Chronic neuritis may either result from incomplete resolution of acute inflammation, or be the continuation of a milder form. In either case it is a frequent cause of certain kinds of neuralgia, of neuroma, and painful subcutaneous tubercle.

Idiopathic neuritis, although much less common than traumatic, is, we believe, more frequent than it is generally considered to be. Its chief exciting causes are exposure to cold, to damp, and particularly to the combination of both; the suppression of profuse perspiration; the arrest of hæmorrhoidal discharges; excessive bodily fatigue; strumous or tubercular affections, and sometimes visceral inflammations and suppurations.

Traumatic neuritis is much more common than idiopathic. As the term implies, it is the result of some external injury, such as wounds, contusions, fractures, dislocations, surgical operations, &c. According to the observations of one of the writers (Dr. L. C.), it is less frequently fatal than the idiopathic form.

Diagnosis.—Although several of the symptoms of muscular rheumatism, of thrombosis or embolism, and of phlegmatia alba dolens have some analogy with those of neuritis, a mistake can hardly be made. Not so always as regards a distinction between a neuralgia and neuritis, but the constancy or permanency of pain in neuritis, and the absence of local signs of inflammation of a nerve in neuralgia, will help the diagnosis, if otherwise obscure.

Treatment of neuritis.—The most important remedies to be employed in the treatment of *acute* neuritis, are the local abstraction of blood by means of cupping or leeches; evaporating lotions or anodyne fomentations; a spare diet with the use of purgatives; tartarated antimony, opiates, belladonna, and the preparations of aconite. When there is reason to believe that the inflammation is of a gouty, rheumatic, or syphilitic character, colchicum, iodide of potassium, or perhaps mercury, should be employed. In cases where it is complicated with serious internal disease, or associated with a low cachectic condition, the treatment must be modified accordingly.

In *chronic* neuritis repeated blisters along the course of the nerve sometimes afford great relief. Anodyne fomentations, and especially liniments of aconite, belladonna, chloroform, and opium, are frequently of signal service. At the same time attention must be directed to the state of the general health. Vegetable and mineral tonics, iodide of potassium, and mild aperients are sometimes indispensable.

In the various kinds of neuritis, either acute or chronic, one of the writers (Dr. B.-S.) has employed, with great benefit, three means of treatment (applications of ice, of the actual cautery, and of descending continuous galvanic currents), which will be described in the second part of this article.

Ulceration of nerves, as a primary affection, appears to be unknown; but nerves in the neighbourhood of ulcers are liable to become involved in the morbid process, and then they are generally the cause of intense and protracted suffering.¹ In such cases, the surrounding soft parts are often enlarged, the skin increases in thickness, the muscles and tendons share in the ulceration, and even the bones increase in dimensions. On either side of their ulcerated portion the nerves are generally thickened, sometimes to nearly double their natural diameter.

When these ulcers are exceedingly painful, Mr. Swan recommends the use of ointment made with powdered opium, or lotions made by mixing well-powdered opium with water, or lime-water. These should be applied on lint, and then a folded cloth moistened with water, or laudanum and water, should be placed over the surrounding skin; at the same time the digestive organs should be regulated. When other remedies have failed, and the disease is confined to the soft parts, excision of a portion of the nerve will be advisable, but if the bone be affected by caries or necrosis, amputation may be necessary. Mr. Swan recommends, that in excising a portion of the nerve, the operation should be performed as far as possible from the ulcer, because there is then a much greater probability that the external wound will heal by the first intention, and that consequently the cut ends of the nerve will escape inflammation and ulceration. It is also advisable to divide the nerve as near the upper part of the wound as possible, as the end of the nerve will thus retract from the wound, and consequently be less liable to become inflamed, should the external parts have assumed this disposition.

Nerves sometimes ulcerate in consequence of the pressure of tumours, &c. A striking case of ulceration of the sciatic nerve, produced by pressure of an aneurism, which extended backward from the right groin, is recorded by Morgagni, *De causis et sed Morb.*, epist. 50, p. 11.

TUMOURS OF NERVES.

All kinds of tumours have been found in connection with nerves, but by far the most frequent is that which constitutes the general group of *Neuromata*. This group is, however, an ill-defined one, as it embraces widely different kinds of morbid growths. For the sake of clearness we will divide what relates to *neuromata* into three sub-groups: 1st, the genuine *neuroma*; 2nd, the various *neuromata*, containing no new nervous elements, but seated in or on a nerve; 3rd, the *painful subcutaneous tubercle*, which only differs from the other *neuromata* by its location and size.

Neuroma.—True *neuroma* has not been known for a long time. Verneuil, in 1854 and 1855, first saw that some *neuromata* contain nerve-fibres of new formation; but it was left to Fuchrer (1856) to establish that there is a kind of *neuroma* almost entirely formed of new nerve-fibres, and that the name of *neuroma* ought to be employed exclusively for that special kind of tumour. Weld and Virchow added to the demonstration the result of their examination of the kind of *neuroma* developed at the cut end of nerves in stumps. They found that swollen end composed chiefly of nerve-fibres. Foerster (1865) went further, and showed that there are two kinds of true *neuroma*, one formed of a substance similar to that of the grey matter of the nervous centres, and containing genuine multipolar and bipolar nerve-cells, with processes going to the affected nerve; and the other formed chiefly of new nerve-fibres spread about in every direction, and mixed in very various proportions with conjunctive tissue. Foerster maintains that the word *neuroma* ought to be kept expressly for those two kinds of tumour, and that the other tumours developed on nerves must be named according to the nature of the tissue composing them: *fibroma*, *myxoma*, &c. No real *neuroma* has yet been found elsewhere than in or on nerves. In some true *neuromata* the different stages of development of nerve-fibres have been found. The fibres of the affected nerve generally remain quite distinct from the new nerve-tubes; they form bundles either on one side of the tumour, or they pass through it when they are not scattered on its surface. Virchow has shown that a true *neuroma* often has other anatomical elements in such a quantity that the tumour, according to the kind of those elements, ought to be called a *glioma*, a *fibro-neuroma*, a *myxo-neuroma*, &c. A true *neuroma* can become a mere *fibroma*, owing to the atrophy of the new nerve-tubes squeezed by fibrous tissue. *Neuroma* is usually a round or oval tumour, varying from the size of a pea to that of a filbert; but it may be as large as a hen's egg. It is generally hard, and has a smooth surface. It may appear only in one place; or it may exist not only on many nerves, but also on most nerves of the body. Virchow divides the true *neuromata* into three groups: the traumatic, the congenital, and the spontaneous. The ordinary origin of a traumatic *neuroma* is a prick of a nerve, the pressure exerted by cicatricial tissue on the cut end of a nerve in a stump, and the ligature of a nerve. Other causes, however, can produce it; such as a section of a nerve, as in a case of Weissmann, or a contusion, as in a case of Dehler.

False neuromata.—This group contains all the cases of tumour of nerves, having the external appearance of a true *neuroma*, and shown to be different only, or almost only, when after extirpation an anatomical investigation is made. As the symptoms caused by a false *neuroma*, and as also the causes producing it, are pretty much the same as those of a true one, there is no possibility of establishing a diagnosis between true and false *neuromata*. But as the treatment is to be the same anyhow, we cannot regret the impossibility of such a diagnosis. Tumours of nerves composed of pure fibrous tissue or fibro-plastic elements are those which are generally mistaken for true *neuromata*; but this has been the case also when the tumour was a *myoma*, a *myxoma*, an *angioma*, or even when it was composed chiefly of fibro-cartilaginous tissue¹

¹ In the second edition of this work, one of the writers (Dr. L. C.) gave the following account of his examination of a false *neuroma*. He says: 'On examination under the micro-

Painful subcutaneous tubercle.—Since William Wood (1812) gave that name to a group of tumours (well described already by Camper and others), it has been ascertained that these morbid growths, as well as the generally small tumours developed in or on a subcutaneous nerve, ought not to be separated anatomically from the neuromata. Their only essential difference is their location, which is entirely under the skin, or partly in and under it, instead of being deeper. They are to be divided into two groups as the other neuromata: the true, composed chiefly or partly of new nerve-fibres; and the false, composed of a great variety of anatomical elements. They are more often due to a contusion than the deeper-seated neuromata.

Symptoms of neuromata.—Sometimes a neuroma, or even a subcutaneous tubercle, is painless, at least for a long time, but even then there is almost always considerable tenderness under pressure of the tumour, and what is more characteristic, there are in a marked degree the peculiar sensations which we will describe as caused by compression of nerves. The existence of a tumour, especially where we know that there is the trunk of a nerve, together with the production of local pain and of those characteristic sensations, is enough for the diagnosis of a neuroma. Generally, we might say almost always, pain exists, and sometimes in a very high degree. The pain shoots from the seat of the tumour, and radiates towards all the parts to which are distributed the ramifications of the nerve. The pain is sometimes continuous, but generally with periods of great and often sudden increase. In other cases the pain disappears at times, and only recurs by attacks of more or less violence. During the paroxysm any contact of the skin in parts receiving ramifications of the nerve increases the pain; but a firm pressure on the trunk of that nerve above the tumour, gives rapid relief. It is not rare that other nerves near, or even at some distance from the diseased one, are sympathetically affected, so that a more or less distant neuralgia becomes associated with the pains of the neuroma. Sometimes local movements are produced during a paroxysm of pain. In other cases local or general hysterical, choreic, or epileptiform convulsions are produced by the constant irritation of the diseased nerve. In cases of subcutaneous painful tubercle, the existence of the tumour is found out more easily than in the case of deep-seated neuromata. It is a source of the most acute pains, which dart like electric shocks along the course of the nerve, sometimes in both a peripheral and central direction. The pains recur very irregularly, and last, at each attack, from ten minutes to two hours or more. They begin gradually, increase in intensity, and gradually decrease, leaving the tubercle and its surrounding parts more or less tender to the touch. They are frequently excited or aggravated by changes in the weather from hot to cold, or the reverse, by storms, &c., and sometimes by mental emotions. The paroxysms may be repeated several times a day, or there may be remissions of days, or even weeks. In all cases of obstinate neuralgia, especially of the extremities, a careful search should be made for the possible existence of subcutaneous tubercles.

Treatment of neuromata and subcutaneous tubercles.—The only effectual remedy for these morbid growths is the knife. The operation will consist of excision of the tumour, with or without a portion of the diseased nerve. When the neuroma is very intimately connected with the nerve, and there is reason to believe that it cannot

scope, it was found to be everywhere composed of a multitude of nuclei, with some nucleated cells, and an abundance of fibrous tissue. Some of the nuclei were more or less oval, but the majority were round, and measured about the $\frac{1}{1000}$ th of an inch in diameter. Amongst these were other bodies of the same nature, but of all degrees of smaller size, and either elongated, angular, or in the form of granules. The nucleated cells were of very small size, and very granular in structure. A few of them were sparingly scattered through the tissue, but, for the most part, they were collected here and there into small, oval, or circular groups. Between these elementary bodies there was an abundance of ordinary fibrous tissue. The fibres were generally more or less tortuous, but parallel, and in their course each divided again and again into finer filaments, which were connected with the cells and with all the other elementary bodies; the granules and the angular or elongated nuclei filling up the interspaces between those that were oval or round; and thus contributing to form with these and the fibres, a close, uninterrupted, and reticular structure.'

be extricated from the nerve without great disturbance or injury, it is better to remove a portion of the nerve with it. With regard to the trunk of the sciatic nerve, which supplies so great a part of the limb, excision of a portion of its length would be attended with serious consequences, and therefore the operation ought to be delayed considerably. If, after the excision has been made for many months, regeneration of the nerve occurs, it may become advisable to amputate the limb.

Tubercle.—Dupuytren and Cruveilhier have spoken of tubercle in nerves, but there appears to be no evidence to prove that it is ever found in this situation as a primary disease; although nerves are sometimes destroyed by the softening of tubercles in which they are involved.

Cancer, unlike tubercle, is frequently met with in nerves, both as a primary and secondary affection. The form of the cancer is in general either the white medullary, or melanosis. It may occur at any part in the course of a nerve, but it is mostly found near its peripheral extremities. It generally grows to a considerable size, as in medullary cancer of the retina. As a secondary disease it is communicated to the nerve by a contiguous cancerous growth.

Dubois, on several occasions, found cancerous growths in the substance of nerves of both the arms and legs. Moutard-Martin saw one on the median nerve, and its removal was followed by cancer of the brain. Dupuytren removed one from the posterior tibial nerve, which, moreover, presented a series of nodulations, like grape-stones. It was the cause of acute lancinating pains. In another case he found the trifacial nerve transformed into encephaloid substance. Cancerous growths have been found, also, on separate branches of the trifacial, on the spheno-palatine ganglion, on the optic nerves, and on the phrenic nerves.

Cysts.—A tumour on nerves may consist of a single cyst containing a gelatinous fluid, or of a larger mass of ordinary structure containing a number of cysts.¹

Hypertrophy of nerves, in the proper sense of the term, has no actual existence as a morbid condition. It is true, as we have already seen, that the inflamed portion of a nerve frequently increases considerably in size; but this increase is the consequence of morbid products and exudations that are poured into the neurilemma and connective tissue between its fibres, which instead of being multiplied or enlarged, sometimes undergo, from compression and impaired nutrition, decided wasting and disintegration.

Atrophy of nerves may be either general or local. General atrophy is found only in cases of extreme and protracted emaciation, from defect of general nutrition. Local atrophy may be the result of several different causes, viz., chronic inflammation, stretching, compression, and even severe contusions. Of these the most common is compression caused by tumours, aneurisms, enlarged glands, &c. Nerves of special sense often waste after loss or wasting of the central organs to which they belong, as the optic nerve after wasting of the globe of the eye. In some instances the nerve-fibres only are implicated, and nothing may be left but the neurilemma; in others the neurilemma itself is involved in a greater or less degree. During the process of atrophy, the nerve-fibres become uneven; their white substance is broken, at intervals, and stripped from their axis-cylinders in masses, which again break up into smaller fragments that are mingled with fatty particles. A spontaneous atrophy of nerves has been studied by Leber, Jaccoud, and others. It has been found chiefly in old age, and in the optic more frequently than in other nerves. No organic cause has been discovered for that special kind of atrophy in which the nerve-fibres become small, dry, rigid, but are otherwise almost normal.

¹ In the Museum of St. George's Hospital (Ser. viii. No. 152) there is a preparation showing a cyst on the median nerve of a patient who had suffered the most excruciating pain in the arm.

INJURIES OF NERVES.

Contusions.—The experimental researches of Tillaux, Weir Mitchell, and those also of Arloing and Tripier, have shown that wounds, producing a paralysis in consequence of a mere contusion of a nerve, do not alter, at least at first, a number of its fibres, and that the degree of paralysis is often due to a temporary pressure on the nerve by effused blood. In man, contusion of nerves rarely occurs, when the parts (skin, cellular tissue, &c.) covering them have not been lacerated. Contusions of nerves are frequently followed very insidiously by the most serious consequences. If the blow be not very severe, the principal change produced in the nerve is the extravasation of blood and other fluids into the connective tissue between its bundles. There is pain, numbness, tingling, or formication in the parts supplied by its branches, followed, in a greater or less degree, by partial and temporary paralysis, and atrophy of the muscles. If the contusion be very violent, the fibres of the nerve may be lacerated or crushed, and then the atrophy and paralysis are of a much more serious character, and may follow the injury either immediately, or not till after an interval of weeks or even months. As we have already seen, tumours are liable to form on nerves that have been contused.

Compression.—Experiments of great value have been made on the effects of compression of nerves by Vulpian and Bastien, Aug. Waller and Weir Mitchell. The two first of these observers, experimenting on themselves, have minutely described the symptoms taking place. Very hard pressure on a nerve of a limb being continued for a long time, they found that during a time of from two to ten minutes, there were cramps, with feelings of pricking and formication, and sensations of heat. A period of diminution of these effects was next observed, lasting from a few seconds to an hour. Next appeared hyperæsthesia, soon diminished and even replaced by anæsthesia, with pains, and especially a burning sensation. Besides, to paralysis soon completed, succeeded a sensation of fatigue. The compression having ceased, the pains and morbid sensations quickly disappeared; but the paralysis and anæsthesia persisted for a variable time, after which voluntary movement became possible. A little later, all kinds of sensibility excepting that to heat and cold returned. The next symptoms were a feeling of coldness arising from the periphery of the nerve, with a sensation of weight rendering movement difficult, and a general *malaise* (uneasiness) increasing sometimes to faintness. Then an extreme excitability occurred, and there were local spasms, with a reappearance of prickly feelings and formication. Slowly the normal state returned. Aug. Waller has obtained very nearly the same effects, but he has ascertained that paralysis appears not only in the muscles receiving fibres from the compressed nerve, but also in some more or less distant nerves. Weir Mitchell agrees with Waller. Some of the symptoms produced in these experiments appear not rarely in people who have had a pressure on a nerve from a wrong position of a limb during sleep, a ligature round a finger or a limb, a bridle in a prolonged ride, the handle of a basket, a crutch (Mitchell's *crutch palsy*), the forceps on the head of a fœtus, or on the pelvic nerves, the head of a fœtus on those nerves, a vicious cicatrix, an abnormal callus, a displaced bone after a fracture or a dislocation, a tumour, an abscess, &c. Of these causes, dislocation of large joints, and the attempts made at reduction, are among the most common. The effects are more serious in proportion to the length of time before the dislocation is reduced. Sensibility suffers much less than the power of motion. If compression of a nerve be severe and long continued, it may give rise to incurable paralysis and wasting of muscles. When the injury is not so severe, it causes pain of a more or less acute, and more or less constant, character, attended sometimes with a feeling of numbness or tingling. Nerves may be compressed, also, by aneurisms; by tumours of different kinds, formed either upon them, or in their immediate neighbourhood; by enlarged glands or bursæ; by abscesses; by cancerous growths; by fecal distension of the rectum and sigmoid flexure of the colon; by hæmorrhoids, and other causes.

Sir B. Brodie relates the interesting case of a man who had severe pain on the inside of his knee. No marks of disease could be detected in the joint, but in the thigh there was an aneurism of the femoral artery. Sir E. Home applied a ligature round the artery in the upper part of the thigh; the tumour immediately ceased to pulsate, and the pain in the knee ceased also.¹ The remarkable case related by Morgagni, of aneurism in the right groin pressing on the sciatic nerve and producing ulceration with intense pain, has been already quoted. Scarpa also describes an interesting case of aneurism of the abdominal aorta, causing disorganisation of the lumbar nerves and injury to the anterior crural and obturator nerves.²

Tumours in the immediate neighbourhood of nerves are frequently, by the pressure which they exert, the cause of as much suffering as those which are formed upon them.

Sir B. Brodie mentions the case of a gentleman who suffered severe and increasing pain in the left leg, from the foot to the knee, in the course of the peroneal nerve. As the limb presented no morbid appearance, the disease went by the name of neuralgia. After a considerable time the patient died of dropsy, and on opening the abdomen, a large solid tumour was found attached to the left side of the lumbar vertebræ. It was evident that this tumour must have pressed on the origin of the sciatic nerve.³ Mr. Travers published an interesting case of compression of nerves by medullary tumour in the ham;⁴ and Sir William Lawrence mentions the case of a tumour in the forearm of a gentleman, situated over the course of the ulnar nerve, and causing exquisite pains, like electric shocks, upwards and downwards, in the direction of the nerve.⁵ Mr. Morris has recorded a most remarkable case of ungovernable satyriasis, excited apparently from pressure on the internal pudic nerve made by a tumour that arose from a blow on the perineum.⁶

Tumours of this description are liable to be mistaken for neuromata, or for those tumours which are formed on nerves or in their substance; but a correct diagnosis may generally be made by moving the tumour in different directions. If the tumour be free, pain will be felt only when it is pressed in the direction of the nerve.

Enlarged glands are not unfrequently the cause of compression and distension of nerves; and there is no nerve so frequently affected in this way as the facial. Several cases of this description were published by Sir Charles Bell.⁷

Sir B. Brodie mentions a case in which 'two lymphatic glands, enlarged to the size of large walnuts, were found situated beneath the skin, on the anterior part of the thigh.' A considerable branch of the lumbar nerves lay over each of these glands, being thus kept stretched like strings of a violin over its bridge, and giving rise to violent pain and convulsive movements of the leg.⁸

The same author mentions a case of severe neuralgia in the foot, caused by the descent and pressure of internal hæmorrhoids, after each evacuation from the bowels.⁹ Romberg calls particular attention to neuralgia of the obturator nerve caused by crural hernia, and gives a long but interesting case in illustration.¹⁰

Pain of a very acute kind is more often excited by small interstitial growths in nerves, than by large tumours over which the nerve-fibres are stretched; for nerves when submitted to a slow distension may be stretched to a very considerable extent without exciting any painful sensation, until they become inflamed, or their nutrition be impaired, when the slightest touch causes acute pain. It therefore seems highly probable that the painful effects of slow compression and distension, by whatever means they may be produced, are in many instances the result of inflammation or some peculiar kinds of irritation which has been excited. When nerves are bruised or otherwise injured at their exit from a foramen or bony canal, they are very liable to cause suffering, because in the event of inflammatory swelling, they are sure to be compressed.

Laceration of nerves occasionally takes place from different kinds of causes, such

as accidents by machines, heavy falls, fractures of bones, dislocation of joints and attempts at reducing them. It is somewhat surprising, that, except in parts that are vitally important, laceration of nerves is not followed by serious consequences so often as might be expected.

Béclard has related many cases of this description.¹ Flaubert mentions a case in which the last four nerves of the brachial plexus were torn from the spinal marrow, by violent extension in attempting to reduce a dislocation of the shoulder-joint. The patient died at the end of eighteen days.² In St. George's Hospital Museum,³ there is a preparation showing the anterior root of one of the cervical nerves torn from the spinal cord, by dislocation of the vertebræ in a heavy fall.

Ligature of nerves.—It sometimes happens that in tying an artery a nerve is accidentally included in the ligature. In certain cases this accident has been followed by severe local disturbance, and even by fatal effects. Many instances of tetanus resulting from the same cause, after amputation, have been recorded by several writers. When pain is referred to the amputated limb along the distribution of a particular nerve, there is reason to suppose that this nerve has been included in a ligature; and if on pulling at the ligature the pain experienced be aggravated, there can no longer be any doubt as to its cause. Under these circumstances, if tetanus or any other alarming constitutional disturbance be threatened, the ligature should be immediately removed.

Hennen gives a most interesting account of the effects of ligatures on nerves, in the case of a general officer who suffered amputation of an arm, which was destroyed by a bullet in action. After the occurrence of fever and extensive sloughing, an attempt at clearing the ligatures was attended with the most excruciating pain. 'He has,' says Dr. Hennen, 'frequently, after the smarting of dressing was over, with great accuracy pointed out on my arm the course of the internal cutaneous nerve, as the site of his ideal pain; often he has described that of the external; and on one occasion, I, with utter astonishment, had the general neurology of my arm and fingers traced by him. Once only did I ever know him to refer his pain to the sensorium itself. On that occasion, from using an artery forceps to the ligature, on which the slide moved rather stiffly, I exerted a greater force than I intended. He convulsively put his hand to the head, expressed a sense of exquisite pain in his brain, involuntary tears dropped from his eyes, a paralytic contraction momentarily affected his mouth, an universal paleness spread over the uncovered part of his body, and he uttered a piercing cry, exclaiming that the agony of his head and mouth was insufferable. The state of collapse was so great, that I was obliged to send an aide-de-camp instantly for volatile alkali and a glass of Madeira, by which he was soon relieved; but the painful sensation, and the prostration of his strength, continued through the day.'⁴

Complete division of nerves.—The effects of complete division, as of other injuries of nerves, vary considerably in different individuals, according to peculiarity of diathesis, or even in the same individual at different times, according to the state of the general health, and other accidental circumstances. In a healthy person, when the external wound heals kindly by the first intention, no remarkable pain or unusual consequences are experienced. Both portions of the divided nerve retract a little, and their extremities, especially the upper one, enlarge and become more vascular, while conglutinal lymph exudes around and between them. In a short time this exudation becomes gradually firmer, and is found to contain cells and nuclei, and then fine nerve-fibres, arising from the extremity of the central portion of the nerve advancing towards that of the peripheral portion, which, on being separated from its nervous centre, undergoes a gradual but rapid atrophy or degeneration. These newly-formed fibres are finer and greyer than those of the central portion of the divided nerve, and it is not till after a period of some months that they become fully developed. According to Ranvier, these fine new fibres descend into the sheaths of the peripheral or atrophied portion of the nerve; but it is a long time before these fibres acquire the normal size and appearance. The same kind of reparative process takes place when a portion of a nerve has been excised, only it occupies a longer period.

³ Series viii. No. 131.

⁴ *Military Surgery*, p. 191.

When the external wound, instead of healing kindly by the first intention, becomes irritable and inflamed, the ends of the divided nerve participate in the inflammation, and give rise to violent pain, spasmodic contraction of muscles, and other severe symptoms. This is what sometimes occurs after amputation when the stump inflames.

Mr. Langstaff has related an exceedingly interesting and instructive case of this description.¹ After amputation at the forearm in a female, the stump did not unite favourably, and she suffered the most distressing agony, which so affected her health, that she became extremely nervous. 'There was a constant state of convulsive action of the muscles of the stump. Everything that could be done to improve her health and relieve pain was fairly tried for several months, without the least good effect. Believing that a second operation was requisite, Mr. Langstaff removed the arm above the elbow-joint, and previous to securing the arteries, drew out each nerve to the extent of half an inch from the surface of the stump, and cut through them to prevent their interrupting the progress of cicatrisation of the integumental parts. The patient was relieved of all her painful sensations, a good stump was made, and her health improved. On examining the amputated part, the median, radial, and ulnar nerves were found remarkably large. The extremities of the two latter were greatly increased by deposition of organised lymph.

Sometimes, after the complete cicatrisation of the external wound by which a nerve has been divided, the cicatrix becomes inflamed, and the nerve participating in the inflammation may give rise to the most acute pain, particularly when the part to which it belongs is put in motion. In other cases one or both ends of the divided nerve may be involved in the cicatrix and be the cause of most severe suffering. The position of the cicatrix is sometimes important, as when it happens to cross at a right angle the tract of a large nerve which is so related to it as in certain positions of the limb to be pressed against it, causing pain and even loss of motion.

Incomplete division of nerves is, in general, productive of much severer consequences than when the division is complete. If nearly the whole thickness of the nerve be divided, the free portions will retract and put the undivided portion on the stretch; but except in peculiar constitutions, under unfavourable conditions, or when the nerve becomes inflamed, this tension does not in general appear to give rise to serious results, as shown by many cases, among which one of Sir Astley Cooper.² But partial division of nerves occurring in persons of a peculiarly nervous, irritable, or hysterical constitution, is frequently a cause of the most distressing local and general symptoms.

Punctures made with different kinds of pointed instruments are the most common instances of this species of injury to nerves. The first symptom which ensues is generally acute pain at the injured part, coming on most frequently at the time of the accident, and darting along the course of the nerves either towards their peripheral extremities or in the opposite direction towards the spinal cord and brain. It is sometimes periodical in its attacks, and attended with redness, tingling, or more or less numbness and swelling of the part. Contractions of the limb, violent spasms or tremors of the muscles, trismus, and even epileptiform convulsions, are not uncommon, and in females hysterical excitement is a frequent consequence. After a time if the symptoms continue severe, the spirits become depressed, there is more or less prostration of strength, and, in some cases, delirium and coma supervene. The pain is often reflected on to other nerves with which the injured nerve is connected only through the nervous centres, and this sympathetic influence is sometimes experienced to a surprising and terrible extent.

Mr. Wardrop has related the case of a woman who pricked the forefinger of her right hand, near the point, with a gooseberry thorn. The wound was immediately followed by great pain, swelling and redness, which in a few days extended along the forefinger and adjoining phalanx of the middle finger. At the end of three months the pain and swelling disappeared, except from the two first phalanges of the wounded finger, which remained extremely painful. The patient's general health suffered considerably, and she had severe nervous paroxysms two or three times a day, during which the pain extended along the finger

¹ *Medico-Chirurgy. Trans.* vol. xvi. p. 140.

² *Lectures by Tyrrell*, vol. iii. p. 171.

to the back of the hand, and between the two bones of the forearm, darted through the elbow-joint, and up the back of the arm to the neck and head, producing a sensation at the roots of the hairs as if they had become erect. To these symptoms succeeded dimness of sight, and subsequently the pain extended to the stomach, producing nausea and vomiting. She had constantly the feeling of a lump in her stomach, and vomited after taking food or drink. At the end of seven months, three incisions were made at the point of the finger, but they gave her no relief. She was afterwards completely cured by amputation of the finger.¹

A case in which the most violent effects arose from the puncture of a nerve during the operation of bleeding, was related to Mr. Swan by Dr. Wilson of Grantham. The patient, who was a woman, had been bled by a gardener. On the second day she fell into strong convulsions, and some time after became comatose. The median vein in which she was bled had not healed, and was somewhat inflamed. An incision was made just above the orifice of the vein, when the patient immediately cried out, 'I am well; I can stir my arm.'

Even fatal effects occasionally follow the puncture of a nerve during the operation of bleeding. Such a case is recorded by Bonetus.²

Incised wounds of nerves are frequently the cause of the same kind of symptoms as those produced by puncture.

Hamilton relates the interesting case of a girl, aged seventeen, and of nervous temperament, who, while cutting bread, wounded the septum between the thumb and forefinger of the left hand. The pain from the first was very severe, became still more so, and extended to the thumb, forefinger, back of the hand, up the forearm, inside of the arm to the axilla, shoulder, and side of the neck. These and other symptoms continued for nearly three months after the external wound had healed, when she got a fright in the street, and fell into an hysterical fit. After two days of hysterical symptoms, all pain and swelling left the arm and never returned.³

This case is a good illustration of the remarkable influence of hysteria in aggravating the effects of local injuries, and affords an example of the singular manner in which these effects are removed by sudden emotions of the mind. Sir B. Brodie, who paid so much attention to this important subject,⁴ justly observes, that when the patients are subject to hysterical paroxysms, sometimes the paroxysms cease on the appearance of the local symptoms, and sometimes, on the contrary, a recurrence of the former is followed by an abatement of the latter, or by complete recovery from them.

He mentions the case of a young lady, who having long suffered from hysterical neuralgia of the hip-joint and thigh, was entirely cured of all her symptoms on being thrown from a donkey.

I knew the case of a girl, who, while suffering from complete hysterical paraplegia, jumped up in a fright, on seeing a mouse run across the room, and was cured from that moment.

For an important case of incised injury of nerves, of which the following is the substance, we are again indebted to Mr. Wardrop.⁵ A young gentleman cut the distal phalanx of the left thumb obliquely across the radial side with a gun-flint. The wound readily healed, but on the patient living freely, in a few days the thumb became painful, and although no change in its appearance could be perceived, and the cicatrix seemed perfectly natural, the pain extended to the forefinger, the radial side of the middle finger, and up the arm as far as the neck and side. The pulse was frequent and tense, the face flushed, and the tongue white and frothy. Copious general bleeding gave almost immediate relief. The symptoms, however, returned and yielded to another bleeding, with copious purging. The paroxysms of pain were several times distinctly produced by mental excitement, and on some occasions were brought on by taking even a small portion of animal food. The wounded thumb, which was at all times painful and extremely tender to the touch, was sometimes seized with paroxysms of agonising pain, which was no longer confined to those fingers supplied by the radial nerve, but extended over the whole hand, arm, neck, and even down the back. Mr. Wardrop divided the injured nerve, with complete abatement of all the symptoms. The success, however, was not permanent, for during several weeks after the operation, whenever he took food of difficult digestion, when purgatives did not readily operate, or when his mind was at all excited, the pain attacked his hand and arm, sometimes severely. After that time he completely recovered. The point of the thumb, however, always remained numb; but whenever the patient's stomach was disordered, he felt pain in the thumb.

¹ *Medico-Chirurg. Trans.* vol. viii. p. 246. Sir B. Brodie has described a case of the same kind, occurring in a young lady eleven or twelve years of age (*Works*, vol. iii. p. 170).

⁴ 'On Local Nervous Affections, and Local Hysterical Affections,' *Works*, vol. iii. p. 133 et seq.

⁵ *Medico-Chirurg. Trans.* vol. xii. p. 205.

This interesting case has several points worthy of particular observation. It affords a good example of acute inflammation excited in a recently injured nerve by a too early use of the part which it supplies, by an incautious mode of living, or by mental excitement. We also see not only that the pain—or rather the irritation exciting the pain—was reflected from the injured nerve to other and even distant nerves with which it is connected only through the medium of the nervous centres, but that even after the connection of the injured portion of the nerve with its nervous centres had been interrupted, pain was still excited in the other nerves by accidental causes. Indeed, in very severe or long-standing cases of traumatic neuralgia, there is reason to believe that the nervous centres in which the injured nerves are implanted, are sometimes secondarily and permanently deranged or diseased, and in this way become the source not only of neuralgia, but even of paralysis in other and distant parts. This view, entertained by the two writers of this article, is also held by Vulpian, Hayem, and other observers. Among other cases that might be mentioned, one important case of complete division of a nerve, recorded by Mr. Swan, is in harmony with this view.

A young lady, aged twenty-three, on December 20, 1822, wounded the ulnar side of the second finger of the left hand, near the middle of the second phalanx, while cutting an orange. The pain extended to the centre of the left breast, and up the left side of the neck to the face, along the branches of the facial portion of the seventh (?) nerve. On the sixth day after the accident the wound had entirely healed, but was extremely tender. The pain was excruciating when she attempted to move the arm with the hand in a state of pronation. Whenever she read, pain was produced in the superciliary nerves of the last side, after about five minutes. As the patient's health was suffering, on January 11, 1823, Mr. Swan divided the digital nerve near the middle of the first phalanx. She was immediately and completely relieved, and could move her arm in any direction without pain; but as the effects of the operation were not permanent, on March 5 the finger was amputated at the joint between the metacarpal bone and the first phalanx, and on examining it at the original wound, a small fibril of the digital nerve was found divided; the end of this next the tip was found incorporated with the cicatrix; the other was formed into a small bulb. At the place of the division of the nerve at the first operation, both its extremities were incorporated with the cicatrix, as with those of the dorsal branch, which had also been divided. Although her local and general symptoms were much relieved by the operation, she continued to feel pain in the hand, arm, neck and face, and about four months later (in July), she began to complain of her spine. About the end of November she complained very much of pain in her back, with tingling in her arms, and a difficulty of supporting herself erect. Percussion along the spine produced uneasiness in every part, and much pain about the lower dorsal vertebrae. Some time after, she was seized with violent pain in the left knee, which lasted for two or three days. Pressure on each side of the spinous processes of several of the vertebrae produced pain, and percussion with a key made it very severe. She had difficulty in voiding her urine. In October 1824, she complained of numbness and loss of sensation in the left hip and shoulder, and of pain at the back of the neck, with a feeling as if the neck could not support the head. At the latter end of the year 1825, and beginning of 1826, she was affected by dizziness, in fits of which she fell down, but never entirely lost her consciousness. Her left arm and leg were weaker than the right. When the membrane lining the left external auditory meatus was touched, cough was produced. Up to March 1829, she had varying degrees of pain and weakness, soreness in the throat with an appearance of venous congestion, and disorder of the digestive organs, with great tenderness in a spot about the size of half-a-crown at the pit of the stomach. She had also some pain and swelling about the uterus and vagina. When sleeping on her left side she very frequently awoke with pain in the amputated finger. *Tic-douloureux* was brought on by either exciting or depressing emotions, by exposure to strong light, and by fits of sneezing, with which she was frequently troubled. When Mr. Swan last saw her on October 30, 1833, she was nearly in the same state as she had been in for a long time; but we are left in ignorance of the subsequent course of the disease. The patient's father had a paralytic attack.¹

Here, then, we have an instance of very extensive neuralgia, of incomplete but extensive paralysis, and other severe symptoms, extending through a period of ten years, as the effects of simple division of a nerve of one of the fingers. That these morbid symptoms arose out of some peculiarity of constitution, there can be no doubt; and it seems highly probable that this peculiarity was of an hysterical character.

¹ Swan, *Diseases, &c. of Nerves*, 2nd edit. p. 120. Of this remarkable case we have given the briefest possible abstract of the most salient and important points, but the details, which are very full, deserve attention.

The symptoms of the various kinds of injuries of nerves due to a wound have been classified in the following manner by Weir Mitchell:—

Early symptoms	{	Defects of mobility . . .	{ From local or general shock. From direct nerve wound.
		Defects of sensibility . .	{ From shock. From direct nerve wound.
Later symptoms	{	Alterations of mobility due to	{ Tonic spasm. Tremor. Paralysis. Joint diseases. Nutritive affections of muscles.
		Alterations in sensibility .	{ Anaesthesia. Analgesia. Hyperæsthesia. Causalgia (burning pain). Neuralgia.
Remote nutritive changes . . .	{	Atrophic change in the skin and its appendages, and in the muscles; eczema; subacute inflammation of joints causing stiffness and subluxations; muscular contractions; altered secretions.	

Foreign bodies embedded in a nerve or pressing against it are often the exciting cause of violent pains and other symptoms similar to those which result from wounds.

Jeffries relates the case of a girl who suffered from violent and almost continual neuralgia of the face for fourteen years. A hard, pointed substance was felt under the skin of the right cheek, and at this point the slightest touch brought on an attack of pain. An incision was made, and a triangular piece of a china cup removed, with complete cessation of the neuralgia.

One of the most interesting and remarkable cases of this description is related by Denmark.¹ A young soldier was wounded by a musket-ball which entered the triceps extensor cubiti, and passed out anteriorly through the bend of the arm. The wound soon healed. The man was subsequently admitted into Hlaslar Hospital, with excessive pain, frightful dreams and startings. The forearm was always bent and in the supine posture. The pain began at the extremities of the thumb, and all the fingers except the little one, and extended up the arm to the part wounded. It was a burning pain, and so violent as to cause a continual perspiration from the face. At his own request, the arm was amputated, with immediate relief, and he was discharged cured in three weeks. On examining the amputated arm, the radial nerve seemed to be blended with, and intimately attached to, the wounded parts, for the space of an inch. It had itself been wounded, and at the place of the injury, was thickened to twice its natural diameter, and seemed as if contracted in its length. On further examination, Dr. Denmark was surprised to find, in dividing the fibres on the posterior part of the wounded nerve, that there was a small portion of the ball firmly embedded in it, which had been driven off by grazing the bone.

It is well to remark about the above case (Denmark's) that there were no convulsions except in the arms, although there were most intense pains. It is a wrong idea that wounds of nerves give rise to general convulsions on account of the pain they inflict. In many other cases, with considerably less pain, there has been general convulsions.

Treatment of injuries of nerves.—When an incised or other open wound is accompanied and followed by very acute pain, by more or less numbness, and by partial or complete loss of sensation and motion in the part beyond the wound, we may conclude that a nerve has been either injured or divided. Under these circumstances it is of primary importance to remove all dirt or other foreign bodies that may be present, to promote healing by the first intention, and enjoin perfect rest. If these precautions are not adopted and the external wound inflames, the nerve is liable to

¹ *Med.-Chirurg. Trans.* vol. iv. p. 48.

participate in the inflammation, and may then become the source of the violent and distressing symptoms already described. When this is the case, it may be necessary to apply leeches to the neighbourhood of the wound, to use either cold lotions or warm fomentations of poppies, and poultices, and to act briskly on the bowels by means of purgatives. When the inflammatory symptoms run high and the constitutional disturbance is considerable, the most decided benefit can be derived from a combination of tartarated antimony, opium, and hyoscyamus, given at short intervals, the antimony being in sufficient quantity to keep up a state of great nausea.

In some cases, after all inflammatory action has subsided and the external wound has completely healed, painful and distressing symptoms may still persist at intervals for a very considerable period; and in other cases where the external wound has healed at once in the kindest manner by the first intention, similar symptoms may supervene. Most of these latter cases are females of a more or less hysterical constitution. But, as we have already seen, there are other causes besides hysteria, such as pressure, dragging, or inflammation of a cicatrix; a premature use of the limb—that is, before the nerve is sufficiently repaired or united; and while the nerve is in this state, it is in some cases very susceptible of irritation by errors in diet, intemperate habits, mental emotions and influences of the most trivial nature. One part of the treatment will of course consist in avoiding or removing the exciting cause, if this can be ascertained. When the cicatrix presses on the nerve, active frictions with moderate exercise of the part will relieve the pain. If it be simply painful or tender, the application of belladonna will frequently allay the irritation; or if it appears to be inflamed, the removal of a little blood by means of two or three leeches may be necessary. If pain and tenderness be experienced in the course of the nerve, blistering, repeated frictions with a piece of ice, or superficial applications of the actual cautery, will afford relief. In cases of that intense *burning* pain (W. Mitchell's *Causalgia*), which is sometimes so agonising, the last of those three means is by far the best. The painful state of the parts to which the wounded nerve is distributed may be treated by the local application of anodynes, such as chloroform, acornite, opium, and belladonna; but the most effectual mode of using most anodynes is by subcutaneous injection, and the best substances to employ in that way are atropia and morphia. Long ago one of the writers (Dr. B.-S.) has used in such cases, and in many others, a solution of those two alkaloids together (from $\frac{1}{16}$ to $\frac{1}{8}$ th of a grain of atropia, with $\frac{1}{4}$ to $\frac{1}{2}$ of a grain of morphia). Mr. Pearson¹ has recorded a very remarkable case of neuralgia, which, after resisting every kind of treatment, yielded at length to the application of a stimulating embrocation that was rubbed into the part for ten minutes twice or three times a day.² In some instances when every other remedy has failed, the happiest effects have resulted from the use of mercury exhibited for a period sufficiently long to affect the gums. Mr. Hamilton has recorded two cases of this description.³ In many instances, however, in which this remedy has been employed, it has completely failed. Another most valuable means of treatment consists in applications of a *descending* constant current of a powerful galvanic machine.

In extreme cases, when all other resources are exhausted, it becomes a question whether a portion of the nerve should be excised, or whether the member which it supplies should be amputated. If the constitutional disturbance be of an alarming character, there should be no hesitation in at once excising at least a small portion of the nerve; for these operations have been frequently followed by an immediate arrest of all the symptoms, as in a case of Dr. Wilson's.

In a case of contused thumb followed by violent symptoms, Sir Astley Cooper removed five-eighths of an inch of the radial nerve with complete success. Mr. Sherwin relates the case of a servant-maid, who suffered from the most alarming symptoms after the operation of venesection. At the end of a fortnight she was cured by a deep incision above the

cicatrix.¹ A similar case with the same result is recorded by Dr. Watson.² Mr. Earle excised about half an inch of the radial nerve, for punctured wound of the thumb followed by pain, spasm, temporary trismus, &c., which had lasted for two months. The patient was soon relieved, and after some months completely cured.

In many instances in which division of the nerve has failed, amputation has been performed with complete success, as in a case of Mr. Wardrop.³ A still more decided example is recorded by Mr. George Bell.⁴ A lady, twenty-six years of age, while cutting a loaf of bread, injured the nerve of the thumb, on the radial side. The wound healed kindly, but was followed by excruciating pain and other violent symptoms. Two years after, on two different occasions, an incision was made through the soft parts to the bone, in the neighbourhood of the wound, but with only temporary relief. Mr. Bell removed the thumb at the second joint, and in five or six weeks she was restored to perfect health.

However, in some cases, especially of females of marked hysterical constitution, neither the division of nerves nor amputation is of any permanent benefit; while in others which have resisted every kind of treatment except by operation, a spontaneous cure has occasionally been effected.

When nerves have been contused or compressed, without becoming inflamed, the best kind of treatment consists of the repeated use of exceedingly hot fomentations, frictions with stimulating embrocations, and Faradisation. But, if tenderness and pain be felt in the course of the injured portion of the nerve, it will be necessary to apply leeches, cold lotions, and blisters, and to insist on perfect rest.

NUTRITIVE AND OTHER CHANGES RESULTING FROM INJURIES AND DISEASES OF NERVES.

(1) *Changes due to Injuries of Nerves.*

In the earlier part of the present century a few observers occasionally and incidentally noticed the morbid effects of injuries of nerves on the nutrition of certain tissues; but it is only within the last twenty years that the subject has been systematically studied. These lesions of nutrition consist chiefly of—

(a) Diminution of temperature in the parts to which the injured nerve is distributed.

(b) Cutaneous eruptions, ulcerations, and alterations in the colour and texture of the skin, and its appendages.

(c) Increase or diminution, and alterations in the quality, of the secretions of the skin.

(d) Various alterations of joints and of bones.

(e) Atrophy and contraction of muscles supplied by the injured nerve.

(a) The effects of injuries of nerves and of nerve-centres on the temperature of paralysed parts was well investigated in the early part of this century by several English observers, particularly by Earle and Yelloly.

Earle excised a portion of the ulnar nerve of a girl for severe neuralgia, and five years after he found the temperature of the paralysed parts decidedly diminished. He also found that they were unable to resist the injurious effects of cold. Frosty weather produced blistering and ulceration of the little finger. Yelloly mentions a case of anæsthesia, in which similar effects were produced by warmth.

Mr. Jonathan Hutchinson, in a valuable and interesting article on 'Injuries to Nerve-trunks,' observes that the parts paralysed by division of the nerve which supplied them, could never, even in the warmest temperature, be raised to that of adjacent, unparalysed parts. 'Nor does even the existence of active inflammation raise the part to the normal standard, although it much increases it.' 'It would appear, therefore, that while a paralysed part can be cooled to almost any extent, it

¹ Duncan's *Medical Commentaries*, vol. iv.

² *Medical Communications*, vol. ii. p. 251.

³ *Medico-Chirurg. Trans.* vol. viii. p. 246.

⁴ *Edinburgh Journal of Medical Science*.

cannot be raised by artificial heat beyond a certain point, and that point much below the maximum of its uninjured counterpart.' One of the writers (Dr. B.-S.) has published a case showing that even twenty years after an injury to a nerve, the temperature of the parts to which it is distributed may remain permanently diminished.¹

(b) Romberg, more than thirty years ago, very clearly described some of the most important nutritive changes that the skin and its appendages undergo, in certain cases of nerve-lesions. He attributed these changes to the cessation of proper supply of nerve influence. This view has been contested by one of the writers (Dr. B.-S.), who has tried to show that the mere cessation of nerve action is not sufficient to produce any of the various alterations of nutrition of the skin which are observed in cases of nerve injuries. He has shown that some irritation of incompletely divided nerves, acting in a direct centrifugal way or by a reflex action, is the great cause of nutritive and secretory changes after nerve wounds. Professor Charcot agrees with him almost entirely on those points, and we cannot do better than refer the reader to the elaborate discussion of this great physiological and pathological question, which will be found in the first volume of lectures of that able physician.² The following facts show the variety of nutritive changes produced by an injury to nerves.

Romberg mentions a case of Dieffenbach's, in which there had been violent pain for ten years in the right foot. On the outer and posterior side of the thigh, near its middle, there was a tumour about five inches in circumference, which was also painful, and, when pressed, augmented the pain in the foot. The tumour was removed, and Romberg saw the patient two weeks after. There was complete anesthesia in the part supplied by the peroneus and tibialis nerves. The muscles of the leg and foot were paralysed. Ulceration appeared early in the heel. Soon after, the nails exfoliated. At the end of three years, Romberg saw the patient again. She rested on the external edge of the right foot, which thus presented the appearance of varus. Further ulceration ensued, with necrosed bone, and desquamation of the epidermis, like psoriasis, the colour of the skin being dark red and shining.³ Hamilton relates a case of Mr. Clampton's, in which puncture of the musculo-cutaneous nerve during the operation of blood-letting was followed by the most severe neuralgia and other symptoms, and the wounded arm became covered with hair.⁴ Larrey mentions the case of a soldier who received a kick from a horse over the right eyebrow. The frontal sinus was fractured, and after some days, cutaneous hyperesthesia and tetanic symptoms of the same side supervened. To Larrey's great surprise, the hair and moustaches of the injured side bristled up and became exquisitely tender to the slightest touch. About a year later the nails became ragged and rough, and fell off.⁵ Similar effects were observed by Bellingeri from a contused wound above the supra-orbital foramen. The hair on the injured side not only became stiffer, but grew with much greater rapidity.⁶ Pouteau records a remarkably interesting case, with symptoms similar to those of Larrey and Bellingeri, and resulting from a contused wound of the supra-orbital nerve.⁷ In a young lady, who came to Dr. L. Clarke with protracted neuralgia of a circumscribed portion of the scalp, the hair over the painful part was not only coarser and stiffer, but perfectly white. Reading, or playing the piano for a few minutes only, brought on the most insupportable and indescribable feelings, radiating as it were from the affected part. In a case of temporal neuralgia mentioned by Trousseau, the hair on the affected side turned white, and acquired considerable stiffness in a very short time.

With regard to cutaneous eruptions resulting from injuries of nerves, numerous interesting observations, besides the one already quoted from Romberg, have been recorded by Rayer,⁸ Earle,⁹ Rouget,¹⁰ Oppolzer,¹¹ Charcot,¹² Raynaud,¹³ Kuhl,¹⁴ Thomas,¹⁵

Paget,¹ Brodie,² Butruille,³ Mayet,⁴ Leloir,⁵ and others. These cutaneous affections have been shown to consist chiefly of erythema, and of vesicular eruptions allied to eczema, erysipelas, and herpes. Sir James Paget has given an excellent description of the erythema observed in cases of injured nerves. 'In well-marked cases,' he says, 'the fingers which are affected are usually tapering, smooth, hairless, almost void of wrinkles, glossy, pink or ruddy, or blotched, as if with permanent chilblains. They are commonly also very painful, especially on motion, and pain often extends from them up the arm.' We will refer for this part of our subject, as also for any kind of alteration due to the nervous system, to the admirable dissertation of Dr. X. Arnozan.⁶

It is to Drs. Mitchell, Morehouse, and Keen, of the United States, that we owe the most precise account of the different morbid changes in the skin, and other tissues, resulting from particular injuries of nerves.⁷ They have shown that the changes in the skin which follow wounds of nerve-trunks are of two kinds. The first is the result of *entire* division of the nerves of the part, with palsy of the whole limb. In most instances there is early oedema of the part. The skin thickens and dries; the epithelium hangs in patches here and there, and is yellow and even pale-brown. These peculiarities, however, are partly the consequence of mere disuse. But the nails become curved as in tubercular disease.

The second kind of pathological change is the result of only partial division of the nerve. The skin is deep red or mottled, or red and pale in patches. The cuticle seems partially lost, so that the cutis is exposed in places. The subcuticular tissues are *nearly* always shrunken. The surface of all the affected parts is glossy, generally devoid of wrinkles, and perfectly free from hair. Sometimes the fingers are dotted with islets of thin and red and glossy skin. This glossy appearance of the skin is always accompanied by pain, generally of a burning character.⁸ 'No particular time can be named as the period at which these changes in nutrition first show themselves. This alone can be said, that they do not belong to cases of complete destruction of the nerves. They may begin within a few days, or at any later date; but usually they arise while the wound is healing.'

If the nerves of the hand be injured, the hair, after some months, disappears from the affected fingers, and the nails undergo remarkable alterations. These alterations consist of a curve in their long axes, an extreme lateral arching, and sometimes a thickening of the cutis beneath their extremities. In other instances the skin at that end of the nail next the third finger-joint becomes retracted, leaving the sensitive matrix partly exposed. At the same time the upper line of union of skin and nail retracts into or under the latter part, and in place of a smooth edge is seen through the nail as a ragged and notched border. 'No deformity of the nails in tubercle at all approaches that which nerve-wounds occasion. Indeed, we think it would be possible for one familiar with these cases to diagnose the existence of nerve-lesion from the form of these protuberant and oddly-curved nails.' When the nails of the toes have been attacked, the curving is as marked, but a distressing ulceration is apt to occur at their angles, and to break out again and again. The best remedy then is excision of the outer edge of the nail, matrix and all.⁹

In a case mentioned by Mr. Jonathan Hutchinson of division of the ulnar nerve, the nail of the little finger, about two months after the accident, came off together with the skin, 'like the end of a glove.' It grew again, but not to more than half its original size.¹⁰ A similar case has been published by Dr. Hayem.¹¹

Among the morbid effects following a nerve-lesion one of the most frequent

is œdema. The experiments of Ranvier, of Boddaërt, and of one of the writers (Dr. B.-S.), have shown how great is the share of a vaso-motor paralysis in such cases.¹

Another important effect of nerve-lesion is the production of an ulcer or of a slough. One of the writers (Dr. B.-S.) has maintained that such alterations are effects of considerable irritation of the nervous centres or of nerves, and cannot be the result of a mere vaso-motor paralysis.

(c) *Alteration of secretions after injury of nerves.*—We have already seen that after the nerves of a limb have been completely divided, the skin is generally dry; but injuries of nerves without complete section modify the secretions in regard both to quality and quantity. The secretion is generally abundant, and sometimes intensely acid, so that an odour like vinegar can be smelt in the neighbourhood of the patient. In one instance the odour of the sweat was 'disgustingly heavy,' and resembled the smell from a bad drain.²

(d) *Various alterations of joints and of bones.*—In the second edition of this work one of the writers (Dr. L. C.) called attention to a peculiar affection, particularly interesting to surgeons, and consisting chiefly in a periodical swelling of joints, the result of both idiopathic neuritis and traumatic affections of nerves. It so closely resembles ordinary rheumatism or gout that it is not easy to point out the distinguishing characters of the two kinds of disease. Remak calls it *arthritidis spuria*.³ Dr. J. K. Mitchell has recorded some very interesting cases of this affection, in the *American Journal of the Medical Sciences* (1831, vol. viii.). It may occur at any time after the first few days of injury to a nerve, and may attack any articulation, or all the articulations of a member. Once fully established, it keeps the joints stiff and sore for weeks or months. When the acute stage is past, the tissues about the articulations become hard, and partial ankylosis results. Of all the agencies which impede movement, it is the most difficult to relieve.

Since the researches of Moritz Schiff, according to which bones in paralysed parts become atrophied only from rest, while, on the contrary, they become larger, i.e. hypertrophied from the effect of a vaso-motor paralysis, many clinical facts have shown that an atrophy of bone may be due to an irritation of nerves, and that hypertrophy does not always result from a vaso-motor paralysis. We will refer to the papers of Avezou, Bouchut, Virchow, Henrot, Weir Mitchell, and others, quoted by Arnozan,⁴ and Dr. J. W. Ogle.⁵

(e) *Atrophy and contraction of muscles from injury of nerves* has been carefully investigated by Dr. Duchenne, de Boulogne. There is always in man, after a time, at least some atrophy of the various muscles to which is distributed a divided nerve. In animals it is not constantly so, as one of the writers (Dr. B.-S.) found long ago, as in one case of extirpation and no reproduction of the facial nerve there was no trace of muscular atrophy in the facial muscles. The difference lies probably in this fact, that the facial nerve in some animals does not contain the vaso-motor nerve-fibres of the facial muscles, while in man the motor and the vaso-motor nerves are in the same trunk. There is no question that in *partial* division or injury of a nerve, there is usually much more rapid atrophy of muscles than after a complete section. Then a whole group of muscles may be affected, or only part of a group; a single muscle only, or even only part of a muscle, which, moreover, may be affected in either a lateral or a longitudinal direction. So soon as the muscular fibres begin to suffer in nutrition, their tension or tonicity diminishes; they become softer, more flabby or relaxed. Sooner or later they begin to waste, and after a time, in many instances, they acquire a kind of morbid tension, and contract or shorten permanently to a greater or less extent, causing a variety of deformities, alterations in the form of the joints, and loss of natural movement. This morbid tension, however, is not always in proportion to the degree of atrophy, for in some instances the wasting is slight

⁵ *St. George's Hospital Reports*, 1871.

while the muscular contraction is extreme. Moreover, a muscle may become shortened from paralysis of its opponent, and this condition must be distinguished from the shortening which is due to atrophy.

Early loss of tone in a muscle, from injury of its nerves, is a bad sign. Rapid diminution of size and contraction, when due to nutritive changes, is still worse. All these changes are ominous of ultimate deformities and permanent loss of power.¹ In the diagnosis and prognosis, no less than in the treatment of injuries to nerves and their consequences, electricity plays a most important part; and for its first application to these purposes, we are chiefly indebted to Dr. Duchenne (de Boulogne). The property of contracting under the influence of electricity he calls electro-muscular contractility. Duchenne has laid down as a law that the persistence of this property is not necessary for the exercise of *voluntary* movements.² In the last edition of his great work (1872, p. 372), however, he says that the electro-muscular contractility always returns soon in paralysed muscles recovering the power to act under the stimulation of the will. On the other hand, muscles that are partially or completely paralysed, with regard to the *will*, may sometimes retain their normal degree of electro-muscular contractility; while in certain cases, muscles which have lost, to a very unequal degree, the power of contracting under the stimulus of electricity, may seem to be all equally paralysed as regards the *will*. There is another remarkable and important practical point to be remembered, viz., that although the retention of electro-muscular contractility is not absolutely necessary for the exercise of voluntary contraction, yet that whenever it is lost, or even impaired, the prognosis is unfavourable in reference to the return of *voluntary* control, and indicates that the affected muscles will suffer in their nutrition and become atrophied. It is curious, however, and very important, that notwithstanding the loss of electro-muscular contractility, the *therapeutical* power of Faradisation may still exercise its influence on the paralysed muscles.

Different forms of paralysis which depend on traumatic affections of nerves, and which may appear to be exactly alike—which cannot, indeed, be distinguished from each other by the ordinary modes of diagnosis—may nevertheless differ essentially from each other with regard to their progress, their gravity, or their termination. The electro-muscular test alone enables us to discriminate those cases in which muscles will remain paralysed and become atrophied in the course of a few months, from other cases in which it may be predicted with certainty that the paralysis, without atrophy of the muscles, will disappear, either spontaneously or by means of Faradisation.

In paralysis resulting from *cerebral* disease, the electro-muscular contractility usually remains unaffected, and therefore Faradisation is of great importance in the differential diagnosis of paralysis which follows injuries of nerves or affections of the spinal cord.

Treatment.—For restoring the paralysed and wasted muscles to their original condition, electricity is unquestionably the most important agent. It should be employed daily for at least ten or fifteen minutes, and each muscle should be separately Faradised. The period when the treatment by electricity should commence must vary according to the peculiarities of the case. If the electro-muscular contractility remain intact, Faradisation should be employed as soon as possible. But when this property is lost—that is, when the nerve-influence is no longer supplied to the muscles, and more particularly when the muscular sensibility is impaired—the treatment by electricity is of no service, and should not be employed until some months after the injury, or until there is good reason to believe that the nerve-lesion is repaired. In addition to electricity, dry-cupping of a whole limb by *Junod's* boot, dry heat after applications of ice, frictions in the direction of the venous current, and shampooing should be employed, with passive motion, to be followed by frequent voluntary exercise of the muscles, as soon as voluntary control is in any degree restored. The douche is often of great service, particularly if hot and cold water be

¹ Mitchell, Morehouse, and Keen, *Gunshot Wounds*, 1864, p. 120.

² *De l'électrisation localisée*, 2^{me} éd. Paris, 1801, p. 330.

alternately used. Care should be taken to preserve warmth in the affected part. When flexion or extension of a limb occurs in consequence of contracted muscles, splints, bandages, and other apparatus will be necessary. If there is the evidence of *neuritis*, a descending constant galvanic current, or the actual cautery, or both, should be used (see *ante*, TREATMENT OF NEURITIS).

When the effects of the nerve-lesion are aggravated or prolonged by some peculiar diathesis, or when the health of the patient is suffering from severe pain and want of sleep, general as well as local treatment must be adopted. Narcotics, iron and quinine, cod-liver oil, and phosphorus are the most worthy of recommendation. The hypodermic method is the best mode of administering narcotics. The combined use of morphia and atropia should be preferred to that of either of these alkaloids alone.

(2) *Changes due to Idiopathic Affections of Nerves.*

Although traumatic lesions of nerves give rise to the most serious nutritive changes in the tissues to which those nerves are distributed, it is not uncommon to find that idiopathic affections of nerves are followed by changes of a similar nature.

The principal alterations in the nutrition of the skin resulting from idiopathic neuritis and neuralgia are manifested in the form of herpetic eruptions. Rayer, we believe, was the first to point to neuralgia as the cause of these eruptions, while other writers, including even Valleix and Cuzenave, regarded the neuralgia as a consequence of the cutaneous affection. Rayer's opinion, however, has been fully confirmed by subsequent observation. The pain is frequently found to precede the eruption, while the latter is sometimes seen to follow the course of the affected nerve.

Barrensprung has recorded a very valuable case, to which we have already alluded, and which proves in the most convincing manner, the close relation between idiopathic inflammation of nerves and herpes zoster. The patient was a child one year old. The eruption extended round one side of the thorax from the sixth to the ninth rib, and after death, which resulted from tubercular disease, the roots of the sixth, seventh, and eighth intercostal nerves, but especially the seventh, were increased in size and of a red colour, in consequence of the presence of enlarged and tortuous vessels in the neurilemma. The diameter of the seventh intercostal exceeded by more than one-half that of the fifth or the ninth. The corresponding intervertebral ganglia were firmly adherent to the intervertebral canal; their connective tissue presented an inflammatory redness, and they were decidedly increased in size.¹

MM. Charcot and Cotard have related the equally interesting case of a woman, aged seventy-eight, from whom a cancer of the right breast was removed in August 1865. In October of the same year, she complained of sharp pains in the right shoulder, and in the right half of the neck. These pains were continuous, but increased in the severity at intervals, during which the patient appeared to suffer the most acute pain. About December 15 of the same year an herpetic eruption made its appearance over the whole right half of the neck, limited exactly, both before and behind, to the median line. The eruption occupied all the other parts of the skin which are supplied by branches of the cervical plexus on the right side, but was not followed by any diminution of pain. The patient died on December 20, after symptoms of effusion into the pleura on both sides. On post-mortem examination it was found that while both the anterior and posterior roots of the spinal nerves in the cervical region were perfectly healthy, the intervertebral ganglia, as well as the compound trunks formed by the union of the two roots, presented a slight tumefaction, and a vascularity which was manifested by a bright red colour. The difference was striking when the corresponding parts on both sides were examined.²

Among the most remarkable cases of neuritis giving rise to herpetic eruptions of the skin are those which M. Leudet, of the Hôtel-Dieu of Rouen, has shown to be caused by the inhalation of carbonic acid.

When the symptoms of asphyxia have subsided, it is not uncommon, after a variable number of days, to find certain disorders both of sensibility and motion. The lower extremities are the parts which are usually affected, although different parts of the nervous system are sometimes involved. In one case, which proved fatal, M. Leudet found the right sciatic nerve at least one-third thicker than the left; its neurilemma was injected, thicker, and more indurated than on the opposite

¹ Barrensprung, *Annal. Charitékrank. zu Berlin*, vol. xi. part ii. p. 93.

² *Mémoires de la Société de Biologie*, 1866, p. 41.

side. In these singular cases, the skin was affected by eruptions similar to herpes. These eruptions appeared almost immediately after the subsidence of the symptoms of asphyxia, and in general, lasted only a short time.¹

Herpes is not the only cutaneous eruption that has been found to follow neuralgia and neuritis, whether traumatic or idiopathic: lichen has been observed by Canuet in cases of neuralgia; ² acne and erysipelas have been seen by Haase ³ and Romberg ⁴ to accompany the same affection. We will refer to the work of Arnozan (already quoted, p. 121 to 142) for a good many interesting cases of various kinds of skin alterations due to nerve-irritation.

DISEASES AND INJURIES OF NERVES.

PART II.

REMOTER CONSEQUENCES OF NERVE-LESIONS.

INTRODUCTION.

TWO distinct groups or classes of symptoms may be caused by a lesion of a nerve ; in one class the symptoms are the effects of the *loss of function* or *cessation of action* of the nerve ; in the other, on the contrary, they are produced by *an action* of the injured or irritated nerve. In the first class, therefore, the symptoms depend on *lack of action*, while in the second, they are due just to the reverse, *i.e. the existence of action*, in a nerve.

Each of these two classes of symptoms may be subdivided. As there are at least four different kinds of nerves, four distinct kinds of symptoms of loss of function or cessation of action may be observed after a lesion of a nerve :

1st. There may be paralysis of motion.

2nd. There may be paralysis of centripetal nerves (sensitive, incito-motor, &c.)

3rd. There may be paralysis of the vaso-motor nerve-fibres, in consequence of which blood-vessels may be distended and full of blood.

4th. There may be paralysis of those special nerve-fibres, which have the power of increasing the activity of nutrition and secretion.

Leaving aside these four kinds of symptoms, I will confine myself here to the study of some of the effects of irritation of nerves. These effects may be grouped under two heads the *peripheric*, or *direct* ; and the *remote*, *indirect*, or *reflex*. Of the peripheric, or direct effects, I will simply say that they give origin to the five following kinds of symptoms, which have been fully studied in the preceding article :

1st. Contraction of muscles.

2nd. Referred or subjective sensations (formication, pricking, feelings of pain, heat, cold, &c.)

3rd. Diminution in the quantity of blood, owing to the contraction of blood-vessels in the part where the injured nerve distributes its fibres.

4th. An increase in the quantity of blood when the irritated nerve-fibres are those having normally the power of increasing the interchange between the blood and the tissues.

5th. In consequence of one or the other, or a combination of the just mentioned kinds of changes in the circulation of blood, there are various alterations of nutrition or secretion in the eyes, the skin, the joints, &c.

Of these five kinds of effects of irritation of nerves, four, *viz.* the first, third, fourth, and fifth, may also be caused either by a genuine reflex action, or by some peculiar influence upon or through the nervous centres. I propose here to treat only of these four last kinds of symptoms.

All the functional affections or disorders, and most of the organic diseases, are frequently produced by an influence exerted upon the nervous centres by an irritation of any part of the length of a nerve. This irritation may occur in the ramifications of a nerve in a mucous membrane or the skin (and be due to worms, a calculus, &c., or to cold) ; or it may depend on an organic or a functional affection of the trunk of a nerve (as in cases of wounds, burns, tumours, or neuralgia). In most instances an

inflammation of the various viscera owes its origin to a reflex influence on the organ which becomes inflamed, proceeding from the irritation of some cutaneous nerve-fibres by a draught of cold air. I will not say more here on this reflex origin of visceral inflammation caused by cold acting on the skin, my object being only to give an outline of the various effects of injuries or diseases of all parts of nerves excepting the network of their terminal ramifications.

Of the various reflex and other remote effects of irritation of centripetal nerves, the following are the principal, of which I propose to speak successively: *epilepsy, tetanus, hysteria, catalepsy, chorea* and other *convulsive affections, trembling palsy, paralysis* of various kinds (*local paralysis, hemiplegia, &c.*), *anæsthesia, deafness, collapse, insanity, delirium, aphasia, coma, neuralgia*, and other *painful affections, inflammation, atrophy, hypertrophy*, and other *morbid alterations of nutrition and secretion*. After having mentioned clear and positive facts, showing that all these affections may be caused by an injury to, or a disease of, a nerve. I will briefly give the rules concerning the diagnosis and treatment of these effects of injuries and diseases of nerves. This essay will therefore consist of two sections: the first, relating to facts demonstrating the existence of a great variety of reflex and other remote effects of irritation of centripetal nerves; the second, giving the principal features and rules of diagnosis and treatment of these effects of diseases and injuries of branches and trunks of nerves.

SECTION I.—AFFECTIONS OF THE NERVOUS CENTRES AND OTHER ORGANS, CAUSED BY AN INJURY TO, OR A DISEASE OF, A NERVE.

Epilepsy.—Of all the nervous and other complaints that may be due to an irritation starting from the trunk, branches, or ultimate ramifications of nerves, very few, if any, are more frequent than epilepsy. Diseases of all the mucous membranes, or their irritation by worms, diseases of the cerebral or spinal meninges, dentition, &c., are known to be frequent causes of this convulsive affection. But it is not so well known, that an injury to, or a disease of, a nerve, not rarely produces epilepsy. Indeed, even a man of great authority as regards epilepsy, Dr. Herpin,¹ has lately maintained that in cases in which this affection seemed to have been caused by an external injury, it was, in reality, due to a disease of the nervous centres. It is most important that medical practitioners should not be misled by such an opinion. The rational treatment of that form of epilepsy which appears after a wound, or an organic affection, of a nerve, would certainly be neglected if such a view were admitted. It is, therefore, necessary to demonstrate that in a number of cases an epileptiform affection and also the most genuine epilepsy have been caused by a lesion of a nerve. This demonstration is given by the following kinds of proof:—

1st. In a great many cases, epilepsy has appeared in persons in whom there was no other cause for its production but a wound, a burn, a tumour, an inflammation, or a neuralgia.

2nd. In a number of the above cases a peculiar sensation, generally misnamed *aura epileptica*, arose from the seat of the irritated nerve before all or most fits.

3rd. In many of the same cases, the application of a ligature round a limb above the seat of the irritation often prevented the occurrence of fits.

4th. In some of the same cases a pressure on the seat of the external irritation invariably brought on a fit.

5th. In many cases of epilepsy apparently due to an irritation of a nerve, the section of that nerve above the seat of irritation, or the amputation of a limb; the extirpation of a tumour, of a cicatrix, of a decayed tooth, of a carious bone, &c., have cured the patients.

6th. I have discovered, in certain animals, that the irritation of the sciatic nerve by a broken bone, or by some other causes (crushing, tying, or cutting), invariably

¹ *Des accès incomplets d'épilepsie*, par Th. Herpin, p. 36. Paris, 1867.

produces a temporary or persistent epilepsy. This convulsive affection never disappears without treatment, unless the irritation has ceased in the sciatic nerve.

These various facts clearly prove that epilepsy may be due to an irritation of a nerve, and exists without any serious organic change in the nervous centres. For the details of cases like those I have mentioned I will refer the reader to the new edition of my work on Epilepsy, which will soon be published. I will only say here, that some of these cases have been observed by perfectly reliable men, such as Sir Astley Cooper, Sir Benjamin Brodie, Dieffenbach, Baron Larrey, &c. I will give one of those cases as a good specimen of reflected epilepsy. It was put on record by Dr. W. Laing of Aberdeen.

M. D., aged twenty-one, had the left hand lacerated by machinery. She went on well till the night of March 6, when she was seized with convulsions, and after a day or two, with trismus and other tetanic symptoms. On April 7 she was dismissed, *cured*; but on June 24 she returned to the hospital. About a fortnight before her readmission she suddenly fell down in an epileptic fit; and since, the attacks have become more and more frequent, recurring five or six times a day, and lasting about five minutes, after which she remained a considerable time in a state of stupor. On the 25th the fits were so severe that she was put in the strait-waistcoat. When the fits were slight, they were confined chiefly to the injured arm. On touching the fingers smartly, the arm was convulsively withdrawn; and when this was done while she was lying in a state of stupor, violent convulsions of the arm were produced. The patient often felt a sensation arising from the injured hand, previous to her fits. As the remainder of the hand was of little use, the fore-arm was amputated: the patient never had the slightest appearance of epilepsy after the operation, and was dismissed cured, a month afterwards. The digital branches of the median nerve, and a branch of the ulnar, were found enlarged to four or five times their usual size, and their extremities bulbous, and firmly embedded in a hard cicatrix.¹

Tetanus.—Referring to the article on TETANUS in the first volume of this work, I will only say a few words on the important questions relating to the nature and to the local treatment of this affection.

I am really surprised that some persons still doubt that it is owing to a peculiar influence exerted, on the circulation of the blood and the nutrition of the spinal cord and the medulla oblongata, by the irritation of a centripetal nerve, that tetanus arises from a traumatic lesion. I hope that the following facts and reasoning will show that this convulsive affection is truly dependent upon an irritation arising from the injured nerves, and not—as Dr. B. W. Richardson, Roser, Billroth, and others are inclined to admit—from toxæmia.

The relation between the wound and tetanus seems to be positively established—at least, in those cases in which the muscles attacked with spasms are on the side injured. Lepelletier, Sir Gilbert Blane, Swan, Dupuytren, and Mr. Curling,² who cites the preceding authors, have seen such cases. My friend Professor G. H. B. Macleod³ relates two cases of fatal tetanus, in which the tetanic spasms were almost entirely limited to the side injured. Baron Larrey states that when the wound causing tetanus is in the anterior part of the trunk, emprosthotonos is the form generally observed.

Other strong arguments in favour of the view that traumatic tetanus is caused by a peripheric irritation, are: 1st, that very frequently the muscles in the neighbourhood of the wound are either the first attacked or the most affected with spasms; 2nd, that in many cases it has been observed by myself and others, that even a slight pressure on the wound or the cicatrix has increased the existing spasms or produced them during periods of relaxation (after chloroformic anæsthesia, for instance).

It may seem strange that tetanus will sometimes follow even the slightest wound, and that it will come at any period of inflammation or cicatrization, and even when there is no pain at all in the wound or its neighbourhood. But this last fact is not an objection to the view that tetanus takes place in consequence of an irritation

¹ Aberdeen Infirmary Reports, in *Lond. Med. Gazette* for Dec. 25, 1840.

² *A Treatise on Tetanus*, pp. 87, 174. London, 1830.

³ See his excellent work, *Notes on the Surgery of the War in the Crimea*, pp. 155–161. 1858.

starting from these parts, as we know that all the morbid or normal influences on circulation and nutrition in the nervous centres, may proceed from the periphery, without any pain, or even without the least perceived sensation.

The kind of lesion which most frequently produces tetanus, implies that there is a great irritation of nerves, although there may be no marked pain. In a table given by Mr. Poland in this work (vol. i. p. 201), I find that out of 1,364 cases of major and minor operations at Guy's Hospital, there was but one case of tetanus; while out of 398 cases of compound fractures and 594 cases of wounds of all varieties, there were 18 cases of tetanus; giving a proportion, when the nerves were simply divided by a sharp knife, of one case of tetanus out of 1,364 patients; and of one case out of 55 patients, after wounds and fractures, when the nerves were bruised or much irritated. In a statistical table given by Dr. Friederich,¹ the influence of great irritation of nerves in causing tetanus is also demonstrated: out of 176 cases of that affection, only 11 occurred after amputation, and 33 after gunshot wounds, while 66 were due to contusion or comminative fracture, and 71 to wounds by puncturing instruments, or dilaceration and bruising of tissues by nails, pieces of wood, &c. Dr. Lawrie's statistics agree with those of Friederich.²

The cases of cure of tetanus either by an amputation of a limb or by section of a nerve, clearly prove the dependence of this affection on an irritation starting from some peripheral part of a nerve. I will refer for a number of facts showing that the section of a nerve can cure tetanus, to a very good review of the meaning of treatment of that affection by Dr. L. G. Richelot.³ The same conclusion flows out from facts like the following, to which I might add a great many others. Tetanus is pointed out to have been caused by a small splinter of bone sticking in the radial nerve (Hennen), by a portion of a whip embedded in the cubital nerve (Dupuytren), by an application of caustic potash on the coraco-brachial nerve (Frère), by shot corns in the tibial nerve (J. Hutchinson), by a splinter of wood in the radial nerve (Morgan), by neuritis (Curling, Lepelletier, Froriep, and others), by ligatures of nerves of limbs (Larrey, Bécларd, Portal. &c.), by a small piece of broken bone passing through the peroneal nerve (Wutzer and O. Weber), by the crushing of the anterior tibial nerve between fragments of broken bone (Alquié), and by partial division or tearing of nerves (Swan, Liston, Billroth, &c.) In cases in which the spinal cord was either inflamed or rendered extremely excitable, the section of a nerve or an amputation has been of no avail; and in some cases, also, in which an inflammation had been propagated high up in the trunk of a nerve, towards its roots, these operations have been useless; but such failures might have been avoided had these modes of treatment been applied earlier, and had all the nerves been divided higher up than they have been. I need not say that the simple division of a nerve should always be preferred to an amputation, unless there are some special reasons for this last operation.

Hysteria.—The extreme frequency of this affection in women renders it difficult to prove that it may be due to an irritation of a nerve. However, there are cases in which it seems quite clear that hysteria was really caused by a wound, or the irritation of a tumour.⁴

Two very interesting cases are reported by Dr. Parsons;⁵ one observed by himself, the other by Dr. S. P. Hildreth.

Morgagni mentions the case of a young girl, who, after a wound to a finger by the biting of a sparrow, was attacked with fits of trembling and screaming, recurring sixteen or eighteen times a day.⁶

¹ *De Tetano traumatico*, Berolins, 1837.

³ *Revue des Sciences Médicales*, publiée par G. Hayem, 1878, vol. xi. p. 300 et seq.

⁴ An interesting case, published by Hamilton (*Dublin Journal*, 1838, vol. xiii. p. 42), shows how careful we must be as regards the signification of symptoms in hysterical patients. All the most characteristic features of neuritis existed in a patient after a wound, but they disappeared at once after a violent fit of hysteria.

⁵ *American Journal of the Med. Sciences*, April 1861, pp. 307, 312.

⁶ *De Sedibus et Causis Morborum*, Lutetue, 1822, vol. vi. p. 613, epist. liv. § 45.

Raynaud relates the case of a woman, who, after having received a blow on the breast, had a first attack of hysteria. Two small tumours soon appeared at the injured place, and for seven years hysterical attacks occurred several times every day. These tumours were removed by Boyer, and immediately after the operation the attacks ceased, and did not recur again.¹

Three years ago, in a patient of mine of a highly nervous temperament, but who never had had any marked symptoms of hysteria, convulsions and delirium, with some degree of lock-jaw, frequently appeared and ceased, during three or four days, after a slight wound by a needle in front of the knee-joint, just below the patella. The needle broke at the time of the accident, and a small part of it remained under the skin. As soon as the pain ceased in the little wound, after the extraction of the point of the needle, the patient got well, and has had no return of hysterical symptoms till she died five years after this accidental hysteria.

Brachet has seen a temporal neuralgia produce hysterical fits every time it appeared, and for all the time it lasted.²

Sir Benjamin Brodie mentions several cases in which a wound was the cause of hysteria.³

A very curious case of hysteria in a man, cured by the removal of a tumour of the external ear, has been published by Dr. Bastien, in his inaugural dissertation.⁴

In hysteria as in epilepsy, an aura starting from some point of the periphery of the body may precede an attack, and also the aura may be created by a pressure on some part. In those cases the same means of treatment as in epilepsy may prove useful. These facts, and the cases I have briefly mentioned, show that hysteria, like epilepsy and tetanus, may be caused by an irritation of a nerve. I must say, however, that a persistent cure of hysteria is very rarely obtained. Various operations, such as extirpations of cicatrices, amputations, &c., to cure hysterical spasms due to an irritation of nerves, have proved beneficial only for a time, in several cases of Sir Benjamin Brodie,⁵ of Mr. Hancock, Tyrrel, and Bransby Cooper.⁶

Catalepsy.—I have seen a case of this affection in which attacks were brought on at once by even a slight pressure on tender spots between the shoulders. *Catalepsy*, therefore, may, like other neuroses, be produced by a peripheric irritation.⁷

Chorea.—St. Vitus's dance may be caused by an injury to a nerve.

In a case of Dr. Borelli, of Turin, chorea was caused by a neuroma of the foot, in a child thirteen years old. This convulsive affection was at once lessened, and in four days cured, after the extirpation of the neuroma.⁸ Andral mentions a case of chorea caused by the irritation of a finger by a retroverted nail.⁹ Dr. J. Malden has cured a woman of choreic movements by the extraction of a decayed tooth.¹⁰ A case of chorea due to an injury to the trunk of a nerve is mentioned by Dr. Ch. Owen Aspray,¹¹ and another due to a wound by Dr. Kingston.¹²

Hydrophobia.—I will try to show elsewhere that the symptoms of this terrible affection depend on a local effect of the virus on the wounded nerves, and that some chance of cure might be obtained by division of the irritated nerves. Already in the last century, G. Hicks proposed this means of treatment against hydrophobia.¹³ I owe to Dr. Stokes, of Dublin, the mention of a most important case, showing that there is good ground to hope that hydrophobia might sometimes be cured by amputation or division of a nerve.¹⁴

Tremulous movements.—The so-called *trembling palsy*, which so often consists

¹⁴ The case above mentioned, and the reasons I have for the hope I have expressed, will be found in the Appendix to my work, *Lectures on the Physiol. and Pathol. of the Central Nervous System*, p. 261 et seq. 1860.

simply in involuntary tremulous movements, without any palsy, may be caused by an irritation starting from a nerve.

Sabatier¹ relates the case of a young man, who, after a wound of the saphenous nerve, near the knee, was attacked with violent trembling of the leg and thigh, which lasted many months. In a patient sent to me by Mr. Erichsen, an injury to a nerve of the left arm has produced trembling in both arms. In another patient, for whom I was consulted by Mr. M. H. Collis, of Dublin, shaking palsy began in a fractured limb, and thence extended to the other limbs. Several cases on record showing that the shaking due to an external injury may become general.²

Rotatory convulsions.—I have found that an injury to the auditory nerve in animals is at once followed by rotatory movements. I do not know of any case of wound of that nerve in man having produced the same symptoms; but several cases are on record in which these movements have been observed in man when the auditory nerve was irritated by an inflammation or some other cause (an injection of caustic, &c.)

I would refer for these cases to my work on the *Central Nervous System*, p. 195, only adding here, that since that publication I have seen five cases of that peculiar kind of involuntary movements, caused by an affection of the internal ear. An irritation of other nerves may produce the same effect. Dr. Kreig relates the case of a patient wounded on the forehead, and on whom a touch of the injured skin produced attacks of exceedingly rapid rotatory movements.³

Local convulsions.—It is well known that wounds of the branches of the fifth pair of nerves may by a reflex influence produce spasms of the muscles of the eyes, or trismus, or histrionic convulsions. It is known also that muscles of the limbs and trunk may be seized with either tonic or clonic reflected convulsions from an irritation of a nerve. Sneezing, hiccup, cough, and vomiting are sometimes also caused by the reflex influence of wounds. Spasms of the sphincters (*vesicae et ani*), of the oesophagus, the larynx, &c., are also among the reflected phenomena not rarely caused by an irritation of superficial nerves.

Contracture of blood-vessels.—Many experiments establish that blood-vessels will contract by a reflex action.⁴ In hysteria and other nervous affections a reflex vascular contracture frequently occurs.

An eminent American clergyman has given me the details of a most remarkable case of prolonged reflex contracture of blood-vessels, he himself being the patient. After having violently struck his leg (two inches above the knee) against a piece of paling-fence, he was soon apparently cured of the local injury; but an influence upon the blood-vessels of the limb showed itself; so that for a whole winter it remained extremely cold, and ever since, for twenty years, its temperature has been lower than that of the other leg. Swan⁵ has also observed a case of permanent reflex contracture of blood-vessels. I will revert to this subject in speaking of reflex muscular atrophy.

Paralysis.—I will not enter here into the discussion of the great question of the mode of production of paralysis when caused by an irritation of a nerve. I will only say that there are two absolutely different kinds of paralysis produced by such an irritation: in one kind a congestion or even an inflammation takes place in a part of the nervous centres by an influence exerted by the peripheric irritation, and the paralysis then produced is accompanied by the usual symptoms of congestion or inflammation of some part of the brain or spinal cord; while in another kind the paralysis exists without any symptom of congestion or inflammation of the nervous centres. This second kind of paralysis caused by an irritation of a nerve I long ago considered as being most likely due, at least in some cases, to a reflex contracture of

⁴ See my researches on this subject, with my friends Dr. Tholozan (*Journal de la Physiol. de l'Homme*, etc. 1855, p. 497) and Dr. J. S. Lombard (*Archives de Physiol. norm. et pathol.* 1868, p. 688).

⁵ *Lor. cit.* p. 167.

blood-vessels¹ in a part of the nervous centres. In the second edition of this work I stated that in some cases, if not in all, paralysis may also depend, however, on a peculiar influence exerted on nerve-cells, in these centres, by an irritation starting from peripheric nerve-fibres, producing what has been called *inhibition*, or, at any rate, changing the condition of activity of these nerve-cells. I have now very good reasons to believe that this mode of production of paralysis is the most frequent, if it is not a constant one, in cases of peripheric wounds acting on a nervous centre so as to generate a loss of voluntary movement. This cause of paralysis may coexist with a persistent spasm of blood-vessels.

Paralysis of the various muscles of the eye, including the iris, is pretty often observed in cases of wound of the infra- or supra-orbital nerves, or in cases of neuralgia. I have seen several cases of that kind of paralysis (caused by a neuralgia), and all characterised by their evident relations with that cause.

In a case, which I have carefully watched, a sprain of *one arm* at the elbow-joint soon produced a paralysis of *both arms*, but more marked in the uninjured arm than in the other. Every change in the degree of pain in the injured elbow was accompanied by a corresponding change in the degree of the paralysis. The pain has now ceased for twenty years, and the paralysis, which ceased with it, has never reappeared.

Baron Larrey states that almost all the men who received slight wounds of the shoulder in the Syrian campaign, were attacked with paralysis of the injured limb. These patients were cured in Egypt, where the air is purer than in Syria. In some, at least, of these cases, the paralysis was clearly due to an influence exerted on the nervous centres by the irritation of superficial nerves.²

Facial paralysis from a neuralgia is not rare; in one case this paralysis and neuralgia were both caused by the irritation of the infra-orbital nerve, and cured by the extirpation of the irritating cause, a piece of porcelain. (Jeffreys, quoted by Tillaux, *Des Affections chirurg. des Nerfs*, p. 15; Paris, 1866.) Fabricius Hildanus, quoted by J. Barthez (*loc. cit.* p. 83, vol. ii.), relates a case of paralysis of one arm, caused by a piece of glass in the ear. The arm may be paralysed by an influence arising from very distant nerves. Drs. S. W. Mitchell, Morehouse, and Keen,³ give two interesting cases, in one of which the irritated nerve was the sciatic, and the other the crural.

Parsons mentions a case of paralysis of the face and arm, caused by a prick.⁴

Roche, in an able dissertation, relates the case of a physician, in whom general convulsions and afterwards complete paralysis of sensibility and motion in the left arm appeared, after the painful extraction of two teeth of the left upper jaw. There was also loss of speech, but no alteration of intelligence. In an hour the paralysis disappeared, and speech returned.⁵

As regards the lower limbs, I will simply refer to my work *On Paralysis of the Lower Extremities*, in which a number of facts show that a peripheric irritation of nerves may produce that form of loss of movement.

I will only say here that one of the lower limbs may be alone paralysed, as in a case by A. Boyer, in which an irritation from a dislocated elbow was (according to all appearances) the cause of paralysis of the corresponding lower extremity.⁶

Cases of more extensive paralysis are also reported by the three American authors I have named. Schenkus (Barthez, *loc. cit.* vol. ii. Notes, p. 41) has seen a case of general paralysis produced by a wound of the eyebrow. I have been consulted by an American officer, who became paralysed in a slight degree in the four limbs, chiefly the right arm and the left leg, from a gunshot wound of the cervical plexus, and partly also of the brachial plexus of the right side.

¹ An eminent physician, trying to ascertain the correctness of a statement of mine, that an irritation of nerves of the kidney may, by a reflex action, produce a contraction of blood-vessels of the pia mater of the spinal cord, was unable to succeed, owing to the fact that, after having laid bare that nervous centre, he vainly looked for blood-vessels on the surface he had under his eyes. Had he waited some time, he would not only have seen blood-vessels appear, where he at first had not seen any, but he might have had the proof that there is a contraction of the blood-vessels of the surface of the spinal cord, powerful enough to render them almost invisible, and occurring when the incito-motor nerves of the skin and other parts of the back are strongly irritated in the operation of laying bare the cord.

⁶ *Gazette médicale de Paris*, 1834, p. 353.

I have seen a most interesting case of general paralysis, caused by an irritation of the nerves of the penis, cured by the successful treatment of balanitis and the operation for phimosis.

Hemiplegia from peripheric irritation is less frequent than partial paralysis or paraplegia.

There are, however, some remarkable cases on record. In one of them, published by Dr. Shearman, there was hemiplegia of the right limbs, caused by tic douloureux of the right inferior axillary nerve. Tonics and galvanisms cured the patient.¹ In another case, reported by Baron Larrey, a lady was attacked with hemiplegia on the same side where she suffered from a facial neuralgia, the hemiplegia being more evident during the attacks of neuralgia; both affections were cured by moxas.²

I have collected forty-two cases in which there was hemiplegia, due to an irritation of either the auditory or the trigeminal nerves near their origin, or of the crus cerebelli. I have tried to show elsewhere that, in those cases, the paralysis which exists in the limbs on the side of the irritated part is probably due to a reflex influence, or to inhibition.³

Sir Astley Cooper mentions the following fact: 'Mr. Toulmin attended a lady on account of her suffering severely from a diseased tooth, and she appeared also to be afflicted with hemiplegia. Mr. Toulmin extracted the tooth, and in a short time the paralytic affection entirely subsided.'⁴

Anæsthesia.—A reflex anæsthesia is not rare in cases of neuralgia.

Many cases of reflected anæsthesia from a wound and other injuries of nerves are on record. A remarkable case of Baron Larrey (*loc. cit.* vol. v. p. 35, 1821), and an important one of Roche (quoted in my *Lect. on the Centr. Nerv. Syst.*, p. 131), particularly deserve to be mentioned. I have observed anæsthesia of the arms in an able lawyer of London, which was caused by a blow on the back of one knee. Several interesting cases have been published by Drs. S. W. Mitchell, Morehouse, and Keen. In one case a shell-wound of the left thigh produced anæsthesia of the right thigh.⁵ I have several times seen anæsthesia of the whole of one side of the face, in cases of neuralgia of one part of the trigeminal nerve on the same side. I have seen also a case of anæsthesia of a part of the forehead and face, in consequence of the irritation of a branch of the fifth pair, on the cheek-bone, by a bruise. In those cases the anæsthesia subsided when its cause was cured.

Amaurosis.—The cases of amaurosis due to an irritation of the trigeminal nerve are frequent enough for my dispensing with quotations of cases. In the first edition of this work I quoted cases of Wardrop,⁶ Notta,⁷ Dr. Noyes of New York,⁸ and Mr. J. Hutchinson.⁹ This last observer has since published several good papers on this subject. I have myself seen five or six cases of amaurosis evidently due to an irritation of the infra- or supra-orbitalis nerve. Cases of amaurosis due to an injury of a nerve of the trunk or limbs are not frequent. Dr. J. B. Colhoun has reported a remarkable case of sudden and almost complete amaurosis of both eyes, caused by a gun shot wound of the scapula.¹⁰

⁴ *Lect. on the Principles and Practice of Surgery*, vol. i. p. 6, 1824. Dr. Castle, of New York, mentions a case of paraplegia caused by decayed teeth, quickly cured by the extirpation of these teeth (*Lancet*, 1846, vol. ii. p. 267).

⁵ See an excellent paper by Dr. S. Weir Mitchell, on 'Paralysis from Peripheral Origin,' reprinted from the *New York Medical Journal*, 1869, p. 59. — I have lately found that the irritation of the sciatic nerve in the lower animal, produces a slight anæsthesia of the lower limb on the opposite side, and of the face and neck on the side of the irritation. It is now pretty clear that reflex anæsthesia, as well as cerebral or spinal anæsthesia, has its principal cause in inhibition of cells and nerve-fibres. On the one hand, many facts show that even anæsthesia due to an organic disease of the nervous centres can be cured by galvanism; on the other hand, I have found that after having produced anæsthesia in a limb by a lesion of the base of the brain, I can not only make it disappear, but replace it by hyperæsthesia through the influence of another organic lesion (hemisection of the spinal cord). See *Comptes Rendus de l'Académie des Sciences*, vol. xc. 1880, p. 750.

¹⁰ *The Medical Examiner*, p. 800, vol. ii. Philadelphia, 1830.

Deafness.—A neuralgia of the face sometimes produces loss of hearing; other kinds of irritation of branches of the fifth pair may also cause deafness. Dentition and decayed teeth have been pointed out as having had the same effects. Pearson relates a case of wound of the thigh in which deafness was among the symptoms produced (*Medical Facts*, vol. vi. p. 109).

Loss of smell, taste and hearing.—The celebrated experiment of Magendie, showing that a section of the trigeminal nerve may produce a loss of the five senses, in the head, is a good illustration of the inhibitory influence an irritated nerve can originate. Magendie had concluded that the trigeminal nerve is a nerve of vision, of audition, &c., not only on account of the result of his experiment, but also because that nerve sends fibres to the eye, the ear, the tongue, &c. Clinical facts have shown, however, that an injury to one branch only of the trigeminal can produce in man the same effect on smell, taste, and hearing, which the section of the trunk causes in animals. So it was in cases of Blondlot¹ and of Bell,² in both of which an injury to the infra-orbitalis at once produced loss of smell and taste, with loss of hearing in one of the cases.

Collapse.—On this important subject I must say that experiments on several species of animals, compared with facts observed in man, have shown me that there are, at least, three different kinds of collapse:—the first, one in which a reflex arrest or diminution of the heart's action predominates; the second, especially characterised by a great diminution of breathing, produced by a peculiar inhibitory influence on the central organs of respiration, the heart continuing to beat with more or less vigour; the third, which was for the first time described in my lectures at the Faculty of Medicine of Paris in 1869, consisting in a powerful influence exerted by the nervous centres on the nerves able to act on circulation, secretion, and nutrition, so as to produce a cessation of most of, if not all, the ordinary interchanges between blood and tissues. In this third form of collapse blood-vessels are generally contracted. But whether they are so or not the blood, instead of being black, in the veins, is reddish and sometimes arterial-looking, and the production of heat ceases in the capillaries. This third form of collapse generally coexists with a diminution of breathing and a weak and often slow pulse. Whatever be the state of respiration and circulation, this is the most dangerous of the three kinds of shock or collapse.³

Neuralgia.—The frequency of *tic douloureux*, caused by an irritation of a small part of the dental nerves, is such, that it is certainly useless to mention cases. But *tic douloureux* may be caused by irritations of other nerves, while also an irritation of the nerves of the jaw may cause a neuralgia elsewhere than in the face. Mr. Harvey has seen a case of *tic douloureux* caused by a tumour of the head. It was ascertained several times that pressure on the tumour brought on a severe attack of tic. The patient was cured by the removal of the tumour.⁴

In the first edition of this work, I gave cases of reflex neuralgia reported by Mr. Gay,⁵ Dr. R. Rowland,⁶ Parsons,⁷ Taignot,⁸ Dr. Greene of New York,⁹ Wardrop,¹⁰ Maréchal,¹¹ Dr. Castle of New York,¹² Marchal de Calvi,¹³ and Romberg.¹⁴ The view

I then maintained, that a neuralgia may be caused by a reflex action, being now pretty generally admitted, I only give here a reference to these cases, and to important publications made on this subject by Ch. Londe,¹ J. Mason Warren,² and Ch. Mauriac.³

Delirium.—I will simply mention here three cases which show quite decisively that delirium may be caused by an injury to a nerve.

A boy, aged fourteen, trod on a piece of glass, which penetrated the big toe, and was completely removed. Four years afterwards, he began suddenly to talk in a very strange, wild way; true delirium set in, and nothing appeased the patient. Near the ball of the big toe a small reddish elevation was found. The moment pressure was made upon it, the seizure returned with violence. An incision was made, and a trifling piece of glass was removed. Much as the patient had raved during the operation, with equal suddenness did all the symptoms vanish; and he was surprised on being told of all the senseless things he had uttered.⁴

I have published a case very similar to this, which I owed to the kindness of the late Mr. Campbell de Morgan, and in which the attacks of delirium took place every time pressure was made on a wound of a toe containing a foreign body. As soon as the irritated part was taken away by the cut of a bit of skin, the patient became rational, and remained so when pressure was made on the wound.⁵

Mr. Sherwin has seen a woman, who, after having been bled, was attacked with pains in the arm, neck, and face, with spasms in those parts, and delirium. After the symptoms had continued a fortnight, a deep incision above the cicatrix quite cured her.⁶

I need not speak here of the delirium that follows amputation or other great operations. The causes are many that bring on delirium in such cases. Among the principal causes I will point out a great loss of blood, and the anxiety of the patient.

Aphasia.—An interesting case shows that this affection also can be produced by an irritation of a nerve. Dr. Guyot has seen aphasia occurring every time an attack of facial neuralgia took place; the patient was cured by quinine.⁷

Inflammation.—Cases of inflammation of the eye due to a reflex action are so frequently met with, that there is no need of proving their existence. Anyone who will read the facts published by Dr. W. Mackenzie, in his valuable work on the Diseases of the Eye, by Mr. R. Taylor,⁸ by Dr. Brondeau,⁹ and by several other more recent writers, among whom I will only quote Dr. J. J. Mants,¹⁰ a pupil of Prof. Donders, will soon be convinced that an inflammation of any part of one eye (the retina, the cornea, the conjunctiva, &c.) may be caused by a wound or an inflammation of the other eye; and that if the first diseased organ is extirpated, the other is often soon cured. Cases of ophthalmia owing to a wound or a neuralgia of the infra- or supra-orbital nerves, or caused by an irritation of the dental nerves, are also not rare. I will only refer to a good case of that kind published by Tavignot.¹¹ Dr. Busschaert has published a curious case of ophthalmia produced by obstruction of the external auditory canal.¹²

Dr. Rowland relates several facts which seem to prove that an inflammation in one side of the brain may be caused by an injury to a nerve in the other side of the body.¹³ To the cases of inflammation of the brain mentioned by Dr. Rowland, I might add several others, among which the most significant have been recorded by

Hennen,¹ R. Bright,² and Champsaur.³ The well-known fact that sometimes, in traumatic tetanus, the spinal cord becomes inflamed, shows that a peripheric irritation may produce inflammation in that organ.

Inflammation of the testicle is also sometimes produced by a reflex action from an irritated nerve, as in cases by Sir Benjamin Brodie,⁴ Barras,⁵ Marrotte,⁶ and others. Sir Astley Cooper⁷ says that by irritation morbid actions are excited in distant organs, and adds: 'thus inflammation is produced in the testicle from irritation in the urethra.'

Inflammation of the abdominal or thoracic viscera may also be produced by a reflex action. Proofs of this assertion are abundantly furnished in Lecture X. of my work *On the Central Nervous System*. A reflex inflammation may be brought on to such a degree as to cause an ulcer, which nothing can heal until the cause (viz. the irritation of a nerve) is removed. Sir Astley Cooper mentions several cases of that kind.⁸

As well shown by Mr. J. Hamilton, there is sometimes in cases of wounds of nerves, a deceptive appearance of inflammation with suppuration.⁹

Coma.—This most dangerous morbid state may also be caused by a peripheric nervous irritation.

In a case of Hirsch, quoted by Dieffenbach,¹⁰ convulsions and coma accompanied local neuralgia, caused by venesection. The patient was cured by two deep incisions over the wound. An immediate cure of coma and convulsions was also obtained in a case similar to the preceding, observed by Dr. Wilson.¹¹ Another case, somewhat similar, has been recorded by Mr. G. Bell.¹²

Apoplexy.—Even apoplexy can be caused by a peripheric irritation.

A remarkable case of wound having caused neuralgia and apoplectic attacks has been observed by Dr. Maupin.¹³ Other cases are mentioned in my old journal.¹⁴

Muscular atrophy.—I have seen a number of cases of atrophy of muscles produced by a reflex influence from an irritated nerve.

In one case *all the muscles of the thumb* wasted very rapidly after a deep wound of the ulnar side of the fore-arm having divided the ulnar nerve. This cannot be explained by the fact that that nerve sends a branch to two muscles of the thumb, as besides these two muscles, all the others, and especially the abductor and the opponens, were notably atrophied. Dupuytren¹⁵ relates a case of reflex atrophy of the forearm and hand caused by a slight wound of a finger.

A neuralgia very often produces atrophy in neighbouring muscles. My friend and pupil, Dr. Cl. Bonnefin,¹⁶ has seen nineteen cases of muscular atrophy caused by a neuralgia. A remarkable fact, observed in those cases, serves to explain how the atrophy was produced—there was a marked diminution of temperature, most likely due to a spasm of blood-vessels. The amount of blood was consequently diminished,

A long list of authors having spoken of muscular atrophy caused by sciatica, is given by Dr. Lagrelette, in his exhaustive work on that kind of neuralgia, entitled *Etude histor. sémiol. et thérapeut. de la Sciatique*, pp. 84–85. Paris 1869. See also Notta's paper in *Archives de Médecine*, sept. 1854, p. 557.

and the wasting occurred owing to the lack of nutritive fluid. Some of the cases of wasting palsy related in Dr. Roberts' excellent work,¹ very likely belong to the class of reflex atrophy.

In a case recorded by Vallez, a wound of the infra-orbital nerve produced a reflex atrophy and paralysis of the face on the same side.²

Atrophy of the cellular tissue.—In some of the cases of atrophy of one side of the face, which Schott and Romberg have called facial trophoneurose, there was an irritation of some sensitive nerve, probably acting by a reflex influence. I saw a case of that rare affection, three years ago in Boston (United States); its probable cause was an irritation of the dental nerves, which produced convulsions in one side of the face (the side where the atrophy was afterwards observed). I will refer for arguments leading to the conclusion that the cellular tissue is alone atrophied in that affection, to the remarkable essays of Dr. L. Lande and of Dr. Frémy.³

Hypertrophy.—Notta mentions cases of hypertrophy of the face and tongue caused by neuralgia.⁴ I have seen a case of considerable hypertrophy of the bones and of the cellular tissue, in the face, which occurred after repeated attacks of neuralgia, in a lady whose general health was excellent.

Various kinds of alterations of nutrition and secretion.—The number of facts that might come under this head has considerably increased since the time that my friend Sir James Paget⁵ first showed how great may be the direct and the reflex influences of the nervous system in disturbing nutrition. *Eruptions* of various kinds (*erythema*, *pemphigus*, *urticaria*, *acne*, and especially the different forms of *herpes*) are often produced by a reflex influence from an irritated nerve, as proved by facts observed by Rayer, G. Simon, Delieux, Notta, Romberg, Hasse, Parrot, and more recently by Charcot, Bürensprung, J. Hutchinson, H. F. Damon, Purdon, and others. I have seen several cases proving clearly the production of certain eruptions by a reflex action. Sir Astley Cooper relates a curious case of *fungoid granulations protruding through an ulcer* in the cheek of a lady, who was quickly cured after the extraction of a tooth.⁶ In a case of *ulcerations* and wasting, probably due to neuralgia, Dr. Hooker cured the patient by dividing the popliteal nerve.⁷ An *erysipelatous redness* and swelling has been seen by Sherwin in a case of wound of a nerve, and a *swelling* of the foot and leg has been observed by Dr. Watson of New York, in a case of a cut of the sole of the foot by a piece of glass.⁸ *Edema* is a frequent reflex effect of neuralgia. Hamilton has seen two cases of that serous effusion after injuries of nerves.⁹ Those persons who know that even *gangrene* may be caused by an influence of the nervous system, as rendered so probable by Dr. M. Raynaud,¹⁰ will not be reluctant to admit that it may be the result of a reflex influence from irritated nerves. Most likely it was not to embolism or to thrombosis, but also to a reflected nervous influence, that gangrene was due in three cases related by Sir William Fergusson,¹¹ Dr. Gubler,¹² and Dr. Grainger Stewart.¹³ The case of Dr. Stewart is especially worthy of attention. I have frequently seen gangrene of the ear appear from a mere prick of the medulla oblongata in certain animals. *Altered secretions* are very often due to a reflex influence in cases of neuralgia, and sometimes in cases of wounds of nerves. *Diabetes* is most likely produced by a reflex

influence when it comes after a peripheric injury. It may be objected, however, that concussion of the brain is then its constant cause. I have not room enough to discuss the question here, but I think that the possibility of a reflex origin to mellituria is clearly established by cases like those reported by Dr. W. R. Hill, in which a burn was the cause of the secretion of sugar.¹ Cases of alteration of hair due to neuralgia or injuries of nerves are not rare, and I could easily mention many, showing changes in colour, in thickness, in abundance, and in rapidity of growth of hair.² *Cataract and glaucoma* have been pointed out also as evidently resulting, in some cases, from an irritation of nerves.³

SECTION II.—GENERAL FEATURES AND RULES OF TREATMENT OF THE VARIOUS AFFECTIONS CAUSED BY AN IRRITATION OF A NERVE.

The following features usually characterise cases of neuralgia, paralysis, epilepsy, and other affections brought on by a peculiar influence, exerted upon, or through, a nervous centre, from an irritation of a nerve.

(1) Previous to the appearance of a more or less remote affection due to such an irritation, the patient has suffered for a variable time from a neuralgia or a neuritis, from a wound or a burn, or from pressure upon a nerve, by either a tumour, a displaced bone, or a foreign body.

(2) An increase or a decrease of the irritation of a nerve is often followed by corresponding changes in the intensity of the remote affections caused by the peripheric nervous irritation.

(3) The various modes of treatment of nervous and other affections, produced by an influence exerted on the nervous centres by a peripheric irritation, are generally quite unsuccessful so long as this irritation persists unabated.

(4) The various affections produced by a peripheric nervous irritation are frequently cured or relieved at once, or very soon after the removal of their cause, viz. the irritation.

I may add a few other characters, more or less implied, however, in the preceding : 1st. When remote affections due to a peripheric nervous irritation occur by fits, it is not rare to see the fit suddenly produced (completely or incompletely) when the diseased nerve is irritated by pressure, or otherwise (application of galvanism, for instance). 2nd. Narcotics, applied to the diseased nerve, will very frequently diminish, at least for a time, the remote affection, even, sometimes, when it consists in, or is connected with, a notable alteration of nutrition.

The above characters may all serve for the diagnosis of remote affections caused by a peripheric nervous irritation ; but the only essential one consists, of course, in the pre-existence of a lesion of a nerve. It must be remembered, that if the trunk of a nerve is inflamed, all the symptoms spontaneously mentioned by the patient may seem to him to exist only at the terminal ramifications of that nerve. There is but one way to ascertain what the starting-point of these symptoms is : it consists in the examination, by pressure, of as much as possible of the whole length of the nerve, from the periphery to the neighbourhood of the brain or spinal cord. Had this rule been applied in the following case, it would not have been published and accepted as a case of reflected influence from a disease of the nerves of the thumb upon the four limbs.

Lady — was attacked suddenly by an acute pain, soon followed by redness and swelling in the left thumb ; and the other fingers gradually were also attacked, and afterwards the forearm. There was contracture and paralysis, with hyperæsthesia. The other arm became affected in a similar way ; and when the pain was violent, there was paraplegia. No benefit

¹ Beale's *Archives of Medicine*, vol. ii. p. 172.

² I found lately that in some animals the division of the sciatic nerve is almost always followed, in two or three months, by a fall of hair in the neck on the side of the lesion.

³ *Gazette des Hôpitaux*, 1846, p. 1 ; *Gazette méd. de Paris*, 1840, p. 180, and 1845, p. 546 ; and De Brondeau's dissertation, *Des Affect. sympath. de l'un des Yeux à la suite d'une lésure de l'autre œil*. pp. 40-40. Paris, 1858.

was obtained from powerful narcotic applications on the left thumb and hand; but the patient was cured after the use of a counter-irritant ointment rubbed over the arm.¹ In this case there had been no injury to the hand; there was no neuralgia; and the symptoms observed in the fingers and the forearm were those we find in cases of local meningitis, or inflammation of the sheath of nerves, at their exit from the spine. I have seen five similar cases, four of which were cured by counter-irritants applied to the spine.

The wonderfully powerful and varied influence exerted by an irritation of a nerve is not due to pain, but to an action of peculiar incident non-sensitive nerve-fibres, as is well proved by two sets of facts: first, that there may be no pain, and even no sensation of any kind, in certain cases in which, however, a peripheric nervous irritation causes a neurosis,² or another affection, as, for instance, in cases of worms in the bowels; secondly, that we every day see cases of pain from neuralgia, or other diseases of nerves, without the production of any remote affection. In only a few cases seen by myself or others, was there such an agonising pain as in a patient, in whom a ball had lodged in the trunk of the radial nerve, producing for many days the most excruciating pain, depriving him of sleep, and causing a continued perspiration from his face, without any other marked reflex action than a contraction of the forearm upon the arm.³

It may seem quite surprising, and perhaps incredible, that the same cause, viz. an irritation of a nerve, will either produce no effect at all, or produce such a variety of affections as I attribute to such a cause. But those who will take the trouble of studying the variety of effects of a clear cause of reflex action, such as, for instance, the exposure of many people to a cold wind when they come out perspiring from a very warm room, will understand that reflex effects may be exceedingly various, although resulting from the same peripheric cause.

Treatment.—Of the various means of treatment of the reflex and other remote effects of the irritation of a nerve, the most important may be classed into two groups—the local and the general means. As regards the local means, they consist chiefly in applications of revulsives or sedatives, or in an amputation or division of a nerve; while the general means consist chiefly in the use of remedies that will diminish the reflex power, or the morbid excitability of the irritated nerve.

Local means of treatment.—Of these means, the best theoretically are also the best practically, according to the mass of facts I have collected. The section of the injured or irritated nerve between the brain or spinal cord and the part of the nerve which is altered, is certainly the most important local means. I hardly need to say, that if this operation is to be performed, the sooner the better, in cases of hydrophobia, epilepsy, tetanus, reflex neuralgia, paralysis, &c. Of course, if there is any reason to fear that the irritating cause will persist after the time necessary for the reunion of the parts of the divided nerve, an excision of an inch or two, which will retard reunion, must be made instead of a simple division. There is no doubt that in a number of cases (especially those of long duration) this operation will not succeed; and there are many discouraging facts showing that the alteration of nutrition produced at a remote distance from the irritated nerve will continue after the division of the nerve, owing to causes yet undiscovered, or to an inflammation of the nerve in a great length between the place of the section and the nervous centres. It would be prudent always to excise at least a very small part of the length of the nerve, to ascertain, by a microscopical examination, if it is inflamed at the place of the operation; as, if such be the case, another division ought to be performed much higher up, and even as near the nervous centre as safely as possible. In a most valuable paper of Messrs. Arloing and Tripier,⁴ they give good reasons for the division of all the nerves of a limb in cases of tetanus; but I do not think that this

¹ Case of Pearson, in *Med.-Chir. Trans.* vol. viii. pp. 252 *et seq.* Pearson does not speak of the spine. Had he examined it, he would have found great tenderness between the shoulders and a little above.

² See my *Researches on Epilepsy*, p. 17. Boston, 1857.

³ Case of Denmark, in *Med.-Chir. Trans.* 1813, vol. iv. p. 48. The patient was cured by the amputation of the arm.

⁴ *Archives de Physiol. normale et pathol.* p. 245, 1870.

radical proceeding is essential in a large proportion of cases of tetanus.¹ Still less would it be essential in most other affections due to peripheric irritation.

There are cases in which, instead of dividing a nerve, all that is necessary is to gain a few days to allow a wound to heal up. I proposed, several years ago, to make use, in those cases, of a simple means, consisting in laying bare the nerve above the wound, and in dropping sulphuric ether upon it. This operation, especially if ether is often applied, may render the nerve, for many days, quite unable to transmit any irritation from the original wound.

Amputation of a limb should never be resorted to with the view of curing reflex epilepsy, tetanus, &c., unless, of course, this operation happens to be necessary for another purpose.

In hydrophobia, besides the section of the nerve at a notable distance from the wound, it would be prudent, after a double section, to withdraw the whole length of the nerve from the place of the upper section to the place of the lower one, which should be near or below the original wound (*i.e.* the bitten part).

Next to neurotomy, subcutaneous injections of narcotics just above the wound, or on the irritated nerve, together with applications of emollient and narcotic lotions, or poultices, on the wound itself, are among the best local means. I have sometimes obtained the cure of chorea, of irregular attacks of convulsions, of *reflected* neuralgia, and even of epilepsy (three cases), by such subcutaneous injections of narcotics in gradually increased doses (from half to two-thirds of a grain of morphia, together with from one-sixtieth or one-fiftieth to one twenty-fifth of a grain of atropine).

I have derived some benefit also in cases of epilepsy with a distinct peripheric aura, from applications of temporary circular blisters, like a ring, around a limb or a finger.

Applications of ether spray, of ice, or even sometimes of a freezing mixture, on the spot where a nerve is wounded or irritated, might be sufficient to produce a cessation of its influence on the nervous centre or another organ. Induction of local anæsthesia by applications of ether spray just upon and above the wound might also be employed with benefit. Before dividing a large nerve, or several nerves, one of these means should be tried.

The actual cautery, applied at white heat, may also be extremely useful. It is perhaps the best, and can certainly be one of the least painful, counter-irritant means.

I need not say that foreign bodies, tumours (neuromatic and others), or vicious cicatrices, &c., giving rise to reflex affections, should be extirpated.

As regards Nussbaum's proceeding, *i.e.* stretching of nerves, I will speak of it in a separate part of this article.

General means of treatment.—After anæsthetics, the most powerful agents to subdue the reflex excitability of the nervous centres are the bromides of potassium and ammonium, belladonna, Indian hemp, aconite, hyoscyamine, ergot of rye, and turpentine; to which list now a few other substances, such as the hydrate of chloral, the chloride of baryum, and Calabar bean can be added. It ought to be remembered that in many cases of reflex affections, the most powerful narcotics, especially opium, and also other remedies, such, for instance, as the chloride of baryum, may be borne in very large doses without any poisonous effect. It would be impossible to say more as regards the general treatment without entering into details which the lack of room prevents my giving, and also because the rules must vary considerably according to the kind of reflex affection to be treated, and the special features of each case.

C. E. BROWN-SÉQUARD, M.D.

¹ The *Boston Medical and Surgical Journal* (March 31, 1870, p. 238) gives a case of severe traumatic tetanus, cured by excision of the internal plantar nerve. Dr. G. E. Foster, who reports the case, stated that 'no spasm of any kind' occurred after the operation.

DISEASES AND INJURIES OF NERVES.

PART III.

SUTURE AND STRETCHING OF NERVES.

IN the previous parts of this article I have said but little of suture, and still less of stretching of nerves. These modes of treatment, especially the last, have lately been used so extensively that it is essential to give a separate account of these therapeutic operations. I will first speak of suture.

Suture of nerves.—Although far less important than it was thought to be for a year or two (1864–1865), this operation is a very useful one. It is perfectly well known, however, that reunion and regeneration of nerves, with return of the lost functions, can take place not only without the suture of the divided ends of a nerve, but also when a long piece of a nerve has been excised and thrown away. Reunion and regeneration can take place twice in the same nerve without suture. I have attended a patient, whose face was not only sensitive, but endowed with a greatly increased sensibility to touch, to tickling, to heat and cold, and to causes of pain, although the infra-orbitary nerve had been twice excised, by Sir William Fergusson. As regards the length of nerve that can be reproduced, I should not like to assign any limit to the regenerating process. I showed recently to the Biological Society the hind limb of a small monkey on whom, in two months and twelve days, nearly the whole extent of the sciatic and tibial nerves had been reproduced, after an excision of twelve centimetres ($4\frac{3}{4}$ inches). The motor and sensory functions had not yet returned.¹

Notwithstanding the denial of Eulenburg and Landois, it is now perfectly well established that suture hastens, or otherwise helps, reunion and regeneration of divided nerves. In comparative experiments which I have made on young animals, I have obtained results very nearly similar to those of Vulpian and Philippeaux, who say that the function of divided nerves without suture will usually return in four or five weeks, while it can take place in seventeen days after suture. I never saw it occur in ten days (Schiff), or in nine days (Magnien). Bèclard, sen., Sir James Paget, and many other surgeons, have seen cases of rapid regeneration and return of function, especially in young patients, when divided nerves had not been submitted to suture. In 1864, an attempt was made to prove that divided nerves can heal by primary union, and recover almost immediately their function, if the cut ends are placed in front of each other and held there by suture. Professor Laugier² announced that, in a case of complete section of the median nerve and incomplete section of the radial, he made use of suture for the median, in the morning, and found, in the evening, that sensibility existed in all the parts receiving fibres from that nerve. A few days after Houel communicated a similar case to the Paris Surgical Society. These cases prove nothing as regards the rapidity of reunion and return of function. Cases are numerous in which a division of one, or even two, nerves of the arm has taken place without loss of feeling in the arm or forearm or hand. Lenoir, Horteloup, Von Burns, Kraussold, Leudet and Delabost have recorded such cases. This is more frequently observed when it is the median nerve

¹ See *Comptes rendus hebdomadaires de la Société de Biologie*, Paris, 1882, p. 80.

² *Comptes rendus de l'Académie des Sciences*, vol. lviii., June, 1864, p. 1139.

which is divided than when it is the radial, and still more the ulnar nerves, which are cut. Sensibility may persist although diminished, even when most nerves of the arm have been divided. So it was in a case of Baudens, in which the radial was almost the only brachial nerve not injured. The explanation of these singular facts has been given by Arloing and L. Tripier.¹ They have proved that the various nerves send to each other recurring ensiform or loop-like fibres, which, coming by one of them from an anterior spinal root, goes into another, to ascend to the spinal cord through a posterior root, producing, when acted upon in one nerve, an impression which follows the loop, and then ascends to the cord through the other, giving rise to the so-called 'recurring' sensation, so well studied by Magendie and Bernard.

It is now quite proved that a *primary union* of the divided ends of a nerve is only an appearance of union, a cicatricial, not a physiological one; that the distal or lower end must pass through the process of degeneration so graphically described by Augustus Waller, and that new elements must be produced. Therefore the importance of suture does not consist in rendering healing easy by preventing degeneration, but in allowing regeneration to take place quicker. In this respect some cases of Verneuil, Gluck, and others are certainly demonstrative; but no case has as much value as one of Mr. Hulke,² in which a sutural junction proved successful fifteen weeks after division of the ulnar nerve. Both bulbous ends of the nerve had to be cut away, and as they were three-quarters of an inch apart, the upper end was stretched and drawn down, and joined to the lower one by silk sutures. The discussion on that case and some others, at the Clinical Society, is well worth reading.

In conclusion I will say—1st. that in recent cases of injury in which there are reasons to suppose that the ends of divided nerves are not very near each other, they ought to be drawn so as to touch each other, and be kept so by suture (catgut sutures to be preferred to silver or silk ones); 2nd. that in cases of injury of nerves, with long persistence of loss of their function, the process instituted by Mr. Hulke ought to be followed, however long the time elapsed since their injury.

Stretching of nerves.—We owe to Professor Von Nussbaum, of Munich,³ the first operation of that kind. He was led to make the trial in a case of most painful and persistent cramp, by two facts, which were not sufficient, however, to authorise the boldness of that new process. He recollected that, in 1860, he had resected the elbow-joint in a scrofulous girl, and released the ulnar nerve from strong adhesions, with the result of curing a contracture of the third and fourth fingers. He also remembered an operation of Professor Billroth,⁴ who had obtained a cure in a case of epilepsy, by dissecting and rubbing the sciatic nerve. Since Nussbaum made his first publication, nerve-stretching has been used, and perhaps abused, in cases not only of mere nerve affections, but also in a great many other affections. Before, however, speaking of the various kinds of disorders or diseases, in which it has been employed, it is essential to say a few words on several questions relating to the effects of stretching on the nerves themselves and on the nerve-centres.

(1) *Weight that can be borne by nerves without being torn.*—Dr. Tillaux⁵ has ascertained on two human corpses that the sciatic nerve, being drawn down, did not break till the weight it had to support was fifty-four kilogrammes in one case and fifty-eight in another. In these corpses the median and ulnar nerves individually resisted till the weight was twenty or twenty-five kilogrammes, and both together till it was thirty-nine kilogrammes. Mr. Johnson Symington⁶ has found that the sciatic nerve can bear a heavier weight than was the case in Tillaux's experiments. Out of fourteen observations on the dead body, in which weights were rapidly attached to that nerve immediately below the gluteus muscle, 130 lbs. (i.e. more

⁴ *Archiv für Klinische Chirurgie*, Wien, Bd. xiii., 1872, p. 379.

⁵ *Des affections chirurgicales des Ners*, Paris, 1866, p. 11.

⁶ *The Lancet*, London, 1878, vol. i. p. 904.

than 60 kilogrammes) was the average weight found necessary to rupture the nerve. The maximum was 176 lbs. and the minimum 86 lbs., in the body of a young female. Gillette,¹ on the dead body of old men, has found that the sciatic nerve breaks, or is drawn away, under a weight of 75 to 100 kilogrammes. In the dead body of a vigorous adult the breaking only took place under the enormous weight of 300 kilogrammes, more than 600 lbs. The median and the ulnar required from 45 to 60 kilogrammes, a weight more than double that mentioned by Tillaux. The following weights are those indicated by Trombetta² as being those required to break the nerves mentioned; sciatic, 84 kilogrammes; internal popliteal, 52 kilogrammes; crural, 38 kilogrammes; median, 38 kilogrammes; ulnar, 27 kilogrammes; radial, 27 kilogrammes; brachial plexus (neck), 22 to 29 kilogrammes; brachial plexus (axilla), 16 to 37 kilogrammes; infra orbitalis, 4½ kilogrammes; supra-orbitalis, 2 kilogrammes and 720 grammes; mental, 2½ kilogrammes. These facts are important in showing the safety of surgeons practising nerve-stretching, as certainly they will not employ a force at all like that which is necessary to tear a nerve, at least in the limbs. My experiments on living animals show, as a rule, that to break the sciatic nerve, a weight superior to that of the body of the animal is necessary. In guinea-pigs weighing from 300 to 400 grammes, that nerve broke only when the nerve was drawn down by a weight above 600 grammes, and in one case more than 700 grammes was required. In rabbits the tearing of nerves is (proportionally to size) easier than in guinea-pigs. In dogs and monkeys it requires always a much greater weight than that of their body to tear the sciatic nerve. In a monkey weighing 3,100 grammes, the sciatic nerve, under gradually increasing weights, did not give way when it had to support 3,650 grammes, but did so under 3,680.

(2) *Extent of stretching that takes place in nerves before they break.*—Tillaux³ says that the median and the ulnar nerves, in man (after death), broke only after having been extended from fifteen to twenty centimetres (six to eight inches). P. Vogt⁴ has not found so great an extension; he has only seen ten centimetres. My experiments on living animals agree more with those of Vogt than with those of Tillaux. The greatest stretching I have seen was on a monkey: it was hardly more than two inches. The ulnar nerve in man and the sciatic nerve in the monkey I experimented upon are of the same size. It is likely from some comparative researches I have made, that the much greater extensibility of the ulnar nerve in a dead body than that of the sciatic in a monkey depends, not on a difference of species, but on the fact that living nerves will break easier than dead nerves, and that, therefore, they cannot be so much extended.

(3) *Changes in structure under stretching.*—It does not require considerable stretching to produce structural changes in nerves. Their lymphatics and capillaries are easily torn, and congestion with serous effusion and ecchymoses are found. This is seen even when there is no greater stretching than by a weight of sixty or eighty grammes (two or three ounces) in a mammal. Somewhat greater distension breaks in pieces the medullary substance of the nerve-fibres. Within two or three days the well-known Wallerian degeneration is already evident in many fibres of the nerve. If the stretching is considerable (250 grammes, for instance, for the sciatic nerve of a guinea-pig, weighing 300 grammes), all the fibres are altered.

(4) *Alteration in physiological properties and loss of function in stretched nerves.*—There is, sometimes, from a slight stretching an increase of excitability in motor and in sensitive nerves. But if the stretching is somewhat considerable, paralysis and anæsthesia, more or less complete, will appear and will last a variable time, according to the degree of structural changes in the nerve. No return of function can be expected in cases in which no trace of amelioration appears before a few days; and as it is clear then that the Wallerian degeneration is taking place, no sign of return of function is to be expected before regeneration has at least begun.

(5) *Mode of influence of stretching of a nerve on the nervous centres.*—Many

² *Sullo Stiramento delli Nervi*. Messina, 1880.

³ *Loc. cit.* p. 12.

⁴ *Die Nervendehnung als Operation in der Chirurg.* Praris. Leipzig, 1877.

experimenters have maintained that no influence is exerted by the stretching of at least most nerves on the nervous centres. If their denial of an influence on those centres concerned only the supposed power of stretching to make an organic change in those centres, there would be no positive reason to dissent from them; but some of them deny also that any other kind of influence is exerted on the nervous centres by the stretching of a nerve. As a good part of the usefulness of stretching as a therapeutic means would have to be doubted if that view were right, it is necessary to show that various kinds of influences may be exerted on the nervous centres and through them to many parts of the body, when a nerve is stretched. In the first place, I will say that for more than three years I have been engaged in experimental researches which show that even a somewhat slight irritation of any nerve containing centripetal fibres cannot be made without at least dynamic changes occurring in all parts of the nervous system, changes consisting in some parts in an augmentation, and in some other parts in a diminution of power. In the second place, we well know that organic changes will occur in the nervous centres, and through them elsewhere, from an irritation, sometimes slight, of almost any nerve having centripetal fibres. This is, I believe, clearly established in the second part of this article (see *ante*, p. 199). In the third place, some experiments on nerve-stretching (which, of course, is a cause of great irritation of that nerve) have clearly shown that the properties and functions of the nervous centres and other parts are modified by that operation. If, for instance, as I have often seen, a transversal section of a lateral half of the spinal cord be made at the level of the tenth dorsal vertebra on a dog or on a guinea-pig, and if then, after ascertaining that, as usual in such cases, there is hyperæsthesia in the leg on the side of the injury to the cord, and anæsthesia in the leg on the opposite side, I stretch without great force the sciatic nerve of the anæsthetic limb, I find that in most cases not only sensibility returns in that limb, but that it soon acquires a morbid degree, so that hyperæsthesia replaces there anæsthesia. Besides, I find also that the limb which was previously hyperæsthetic becomes still more so. A clearer proof of a great change in the spinal cord could not exist. In the fourth place, I will say that in many cases of considerable stretching of the sciatic nerves in guinea-pigs, I have found the toe innervated by fibres from the crural nerve, anæsthetic like the other toes which receive their nerve fibres from the sciatic. Sometimes even the leg on the opposite side to that of the operation becomes also anæsthetic. In one case there was an incomplete paralysis and anæsthesia in the right leg after considerable stretching of the sciatic nerve on the left side. It is clear, then, that the spinal cord is modified by stretching of a nerve. I will only add that, if a slight stretching can increase the power of the spinal cord, as regards sensibility, the same operation, if very energetic, will diminish or destroy for a time the power of that organ as regards that property.

I now pass to the examination of cases in which stretching of nerves has been used as a therapeutic means against various affections.

a. Nerve-stretching against neuralgia.—There is no doubt that a number of cases of inveterate neuralgia have been treated with success by that process. In a valuable paper of Mr. W. J. Walsham,¹ cases are mentioned in which the cure yet persisted after five months (two cases, one of Mr. Walsham, one of Dr. G. Stewart), seven months (one case of Mr. Spence), fourteen months (one case of Mr. Callender), eighteen months (one case of Mr. Bartlett). After nerve-stretching in many other cases, the cure had not perhaps been long enough to be sure that it would be permanent, inasmuch that the cessation of pain very frequently is only due to the structural lesions caused by stretching, and it is to be feared that, after regeneration in those cases, as in those of neurotomy, the neuralgia would return. It is evident that, of the two surgical processes in cases of neuralgia, neurotomy and nerve-stretching, the last is the most useful, and that which offers the least danger especially for certain nerves: the infra-orbitalis particularly. Still I hold the opinion that certain modes of treatment are more powerful than nerve-stretching. I will refer to the second part of this article

¹ *British Medical Journal*, 1880, vol. ii. p. 1009.

(see p. 213) for the prescription of a narcotic subcutaneous injection, and for the rules as regards the use of the actual cautery. These means employed simultaneously leave so few cases of neuralgia uncured, that they ought to be tried before having recourse to nerve-stretching. It is not so in those terrible cases of so-called epileptiform neuralgia, such as was that of Mr. Walsham, and as was also a case of Dr. Grainger Stewart.¹ Nerve-stretching is then one of the very best means. In Dr. Stewart's case, the stretching of the infra-orbitalis proved insufficient, and the cure was obtained only after the stretching of the mental nerve. In cases of ordinary, although violent, neuralgia, it may not be necessary to stretch more than one nerve, even when a number of others are affected. This is clearly proved by a case of Masing,² in which almost all the branches of the trigeminal were attacked, and in which, however, a cure was obtained by stretching the infra-orbitalis alone. This fact is important in showing that the stretching of one nerve can, through the nervous centres, affect other nerves. Another point of some importance seems to come out from a case of neuralgia, in which the sciatic nerve was stretched by Morton without any marked benefit, and which was cured by excision of part of that nerve. In all cases in which excision is to be resorted to, there would be some benefit in stretching the nerve before practising excision.³ Pooley⁴ gives as a reason in favour of nerve-stretching in neuralgia, the probability of ameliorating the trophic troubles which often exists in that affection. This is right if stretching is sufficiently strong to alter all the fibres of the nerve, as then they are exactly as if the nerve had been divided—a condition which leads to the cessation of the trophic disorders, which, as I have established, depends not on the absence of a supposed favourable nervous influence, but on the existence of a mischievous influence exerted on nutrition by an irritated nerve.

b. Nerve-stretching in cases of spasmodic tic and local tonic spasm.—The first case of this kind is the one in which, for the first time, stretching was used by Nussbaum.⁵ From blows on the nape of the neck and the elbow, a man had contracture of the muscles of the thorax, and of the arm, forearm, and hand. The ulnar nerve and several branches of the cervical and brachial plexuses were stretched and the patient was cured. Gartner, according to Nussbaum,⁶ stretched, with some success, the brachial plexus in a case of rigidity and great pains. In a remarkable case of blepharo-spasm with neuralgia, Professor Panas⁷ obtained a cure by stretching the infra- and supra-orbitalis. Kocher⁸ and others have had a similar success in cases of blepharo-spasm. So far the cases of spasmodic facial tic have not found in nerve-stretching a very useful means of cure. A good paper of Bernhardt⁹ contains three cases of stretching of nerves, twice against tic, once against spasm of the muscles supplied by the spinal accessory. A very slight or only temporary amelioration was obtained in the first two cases, and no amelioration at all in the last case. In the two cases of facial spasmodic tic the nerve stretched was the facial. In other cases the nerve extended was a branch of the trigeminal. It is clear that if the operating surgeon, in Bernhardt's cases, had drawn sufficiently on the facial nerve, he would have produced an alteration equivalent to the section of the nerve, and would then have had at least a temporary cure, but at the expense of a paralysis of more or less long duration. The same thing can but partly be said of the case of spasm of the muscles innervated by the spinal accessory. I say 'partly,' because those muscles receive some nerve fibres from other sources, so that even the section

⁹ *Zeitschrift für Klinische Medizin*, Berlin, Bd. iii. 1881, p. 100.

of the spinal accessory nerve is not always followed by an absolute cessation of the spasmodic movements of the neck and other parts. Mr. F. A. Southam¹ was more fortunate than Bernhardt, as he obtained an almost complete cure in one case of stretching of the spinal accessory against torticollis, but he gained only a very slight improvement in another case. He and others² were successful in cases of spasmodic jerking of the facial muscles. There has been a facial paralysis in most of, if not in all, the cases of stretching of the facial nerve. In the case of Dr. Allen Sturge, and Mr. Godlee, although the nerve was extended 'with moderate force' (but this was repeated till paralysis appeared), two months after the operation the paralysis was still complete, and began to yield only after three months, but then improved rapidly. In Schlüssler's case, as well as in two cases of Eulenburg, and that of Putnam's, the paralysis lasted many months. In the cases of Baum, it is the more surprising that the paralysis only lasted eight days, that Baum had thought fit to crush the nerve with the forceps. The paralysis began to disappear after five weeks in Mr. Southam's case. I believe I can conclude that there is no affection in which nerve-stretching has proved as favourable as in spasmodic tic without much neuralgic pains.

The attempts made so far in cases of pains and spasmodic rigidity with hemiplegia have not been successful enough to give much encouragement. I have seen in a monkey, paralysed from brain disease, an excessive rigidity disappearing completely (gradually in two days) in the hind limb after stretching of the sciatic nerve; but the contracture returned in a few weeks and hardly diminished after a renewed stretching. Nicaise,³ on a hemiplegic patient of Dr. B. Ball's, stretched the sciatic nerve to the extent of seven centimetres, without any marked effect on either the pains or the contracture of the paralysed leg. Czerny,⁴ in a case of hemiplegia with pains, convulsions, and rigidity of the arm, was somewhat more fortunate. He first stretched the axillary plexus, and found that the rigidity diminished, and that the movements became easier; but after stretching the supra-clavicular plexus, the paralysis increased. There was, however, a complete cessation of very troublesome convulsions of the arm. In cases of rigidity or convulsions due to affections of the spinal cord, *without locomotor ataxy*, a somewhat favourable result has been obtained twice from stretching of the sciatic nerve. In a case of double lateral sclerosis, Mr. Southam⁵ obtained this most remarkable result, that although the nerve was stretched on one side, the shooting pains disappeared from the two lower limbs; but the rigidity diminished only in the limb operated upon. In a case of Nussbaum's⁶ there were clonic convulsions from the knee to the thorax with intense pain, owing to disease of the lower part of the spinal cord. Stretching of the sciatic nerve on one side cured the spasms and pains on that side; the same operation on the other side acted in the same way on the symptoms in this last side.

Nerve-stretching in tetanus.—As this subject must be fully treated in the article on TETANUS, I will only make the few following remarks:—1st. That the proportion of cases in which a cure of tetanus was obtained by, or at least after, nerve-stretching (even sometimes when the symptoms were quite severe), is too large for our rejecting that mode of treatment, notwithstanding the sharp, but in a measure only, well-founded criticism of Mr. Henry Morris⁷; 2nd. That even in cases of failure there was often a considerable amelioration from that means of treatment, so that there is ground to think that it might be of great service if used together with some powerful

⁷ *British Medical Journal*, 1879, vol. i. p. 933. Out of the number of cases I know of, that is twenty-three, there has been eight cases of recovery and fifteen failures,

internal remedies; 3rd. that, as pointed out by Dr. A. W. Johnstone,¹ it is essential to stretch all the nerves supplying the part, whose injury has caused the disease; 4th. that the operation should be made early and as high up as possible, if there is any suspicion of the nerves being inflamed near and at some distance from the wound, burn, or other injury; 5th. that stretching ought always to be strong enough to destroy the power of transmission of sensitive impressions in the nerve operated upon.

Nerve-stretching against an epileptiform affection.—The case of Billroth (already quoted) in which he pressed upon and rubbed a nerve has led Dr. Czerny² to stretch a nerve in a case of epilepsy. There was an aura starting from the hand and the ulnar nerve was stretched. There was no favourable effect. No hope of a cure can exist in cases of epilepsy by nerve-stretching, excepting those in which a clear peripheral cause exists.

Nerve-stretching against paralysis, anæsthesia and lepra anæsthetica.—A remarkable case of cure of paralysis, due to a fracture of the humerus, has been published by Mural³. The ulnar nerve was stretched and the cure rapid. In another case of traumatic paralysis the stretching of the ulnar and the median nerves led to a cure. A wound had caused paresis of some muscles and anæsthesia of the thumb and index and partly of the medius. One day after a slight stretching, sensibility had returned to its normal degree, and later on the muscles of the thumb recovered their action, but the extensor muscles remained paralysed.³ In a case of slight wound having healed badly there was a paralysis with atrophy of some muscles of the hand. Slight stretching of the ulnar nerve was followed by a gradual return of muscular action in the paralysed parts.⁴ In a case of paraplegia, with total loss of motion and sensibility, both sciatic and crural nerves were stretched on the two sides, and the patient, who for years had been confined to his bed, was able soon to go about on crutches, the paralysed limbs supported mechanically.⁵ Unfortunately, no detail is given as regards the return of power and feeling, and it is a question whether the possibility of going about was not due simply to the immediate cessation of spasmodic movements. In a case of anæsthesia and paralysis of both lower limbs, from neuralgia on one side, Masing stretched the crural and sciatic nerves, and the patient ultimately was cured of the neuralgia, the anæsthesia, and the paralysis.⁶ In lepra anæsthetica most remarkable effects of nerve-stretching have been obtained by Dr. Laurie⁷ especially. He has treated thirty cases of that affection by that process. On all the patients there was a more or less favourable result; but for how long is not known. In the first case sensibility returned in the arm after the stretching of the ulnar, the hand became stronger and the thickening of the nerve disappeared. Dr. Laurie operated on the sciatic nerves and the two ulnars in one case, and obtained a return of movement and sensibility, especially in the upper limbs. Dr. G. Bomford⁸ stretched both ulnar nerves in a case of great atrophy, paralysis, and anæsthesia from leprosy. There was a rapid return of movement and sensibility, the atrophy persisting, however.

Nerve-stretching in locomotor ataxy.—Carl Langenbuch⁹ was the first who tried to ameliorate or cure that affection by that means. That first attempt deserves to be noticed somewhat at length:—

A man of forty had lightning pains and locomotor ataxy in the four limbs and had lost feeling, chiefly in the lower limbs. His pains were so great that Langenbuch decided to stretch the most attacked nerve, the left sciatic. The operation was performed on September 13. The pains in all parts supplied by that nerve disappeared at once. There was some

paralysis, which in a few days disappeared. On September 25 the two crural and the right sciatic were stretched. There was no more pain in the lower limbs. When the patient tried to walk, after a few days, he found that he had recovered some feeling, and it was ascertained that the ataxia had ceased. Later on he came to have the same operation performed on his arms, but died suddenly in a fit of epilepsy (P), when chloroform began to be given to him.¹ Esmarch has obtained a favourable result in a case of ataxy in which he stretched the brachial plexus. The pains and ataxia disappeared. Erlennmeyer,² in a bad case of tabes dorsalis, stretched the right sciatic nerve to the extent of six or seven centimetres. Ten days later the left sciatic was also stretched. There was no improvement of the various symptoms, except that the muscular power became greater in the legs. Erlennmeyer believes that he did not stretch the nerve enough in his two operations. Drs. Debove and Gillette³ relate that in a very bad case of locomotor ataxy in the four limbs, one of the sciatic nerves was stretched, and that the result was most remarkable: the pains disappeared everywhere; sensibility returned; the muscular sense improved; the incoordination was diminished, but walking remained extremely difficult on account of an excessive atrophy of the legs. In a second case Debove and Gillette, chiefly against the pains which were intense in the two upper limbs, stretched the radial and median nerves on the right side. The pains almost entirely disappeared everywhere; the anæsthesia diminished in the left foot, the incoordination improved notably, and walking became possible without help. Dr. Sury Bienz⁴ in a case of ataxia, with violent pains, obtained very favourable results from stretching of the sciatic nerve. Schlüssler⁴ of Bremen, is said to have effected a complete cure, in a similar case, through the same means.

General features of nerve-stretching and its curative importance.—Some points clearly established by experiments on animals (chiefly mine and those of Tarchanoff) are strongly supported by clinical observation. *First*, stretching of a nerve acts on the nervous centres, and through them on more or less distant nerves. Most of the cases of nerve-stretching in locomotor ataxy especially show this; none as much, however, as the second case of Debove and Gillette, in which there was a great effect produced on the whole spinal cord by the stretching of the two nerves in one arm, and a more considerable amelioration in the foot and arm on the opposite side than in those on the side of the operation. Panas justly grounds the superiority of stretching over neurotomy on the favourable influence of the first operation on the nervous centres, in cases of neuralgic pains and spasms. It results forcibly from many facts that, even in cases when neurotomy is preferred, some pulling of the proximal end of the nerve (after the division) ought to be exercised. A proof of the superiority of stretching over neurotomy is found in a case I have quoted of Masing, in which stretching of one branch of the trigeminal has cured a neuralgia of almost all the branches of that nerve. It is especially in cases of nerve-irritations producing mischief through the nervous centres, that nerve-stretching is to be selected rather than neurotomy. *Secondly*, experiments on animals show that there cannot be a considerable degree of nerve-stretching without a structural alteration of the nerve, rendering the operation equivalent to neurotomy. This is also proved to be the case in man. A clear conclusion flows out from this fact: it is that in cases of neuralgia, of painful or unfelt local spasms or twitchings, when it is important to produce anæsthesia or paralysis, for a time at least, it is well to draw considerably on the nerve, keeping in view that, if stretching is performed, as it ought to be, by means of a weight suspended to the nerve, there will be an alteration of tissue, sufficient to produce a loss of function, under a weight somewhat less than that which will break the nerve (see *ante*, the indications given of weights necessary to tear or to root out the principal nerves); *thirdly*, regeneration of nerves is more rapid in altered nerves after stretching than in divided nerves; this is established as well by experiments on animals as by facts observed in man.

In none of the various affections in which nerve-stretching has been used is it called for so much as it is in that incurable or almost incurable affection, *lepra anæsthetica*. The failure of other means renders the benefit obtained through nerve-stretching in that affection a very great blessing. In another kind of nerve-trouble, in which treatment generally fails also, *i.e.* in traumatic paralysis and anæsthesia,

¹ *Berl. Klin. Woch.*, April, 1880, p. 235.

³ *Gazette Hebdomadaire, de Paris*, 1880, p. 823.

⁴ Quoted by Wiet, *loc. cit.* pp. 139 and 140.

there has been what I may call wonderful successes obtained by nerve-stretching. Locomotor ataxy comes next in the series of affections in which our means of cure are limited, and in which, therefore, any new serviceable means of treatment must be welcome. Either because the cases of failure of amelioration by nerve-stretching have not been published, or because that means is really most valuable, we know almost only cases of improvement or cure (?), as the list I have given shows. Tetanus, by the same reasons, comes next. As regards cases of spasmodic tic, painless or painful, as in the epileptiform neuralgia, some distinction must be made concerning the kind of nerves on which stretching is used, and also the degree of stretching. The good effects obtained by pulling on a sensitive nerve (the branches of the trigeminal) seem to be much less than those given by the same operation on a motor nerve (the facial). If there is much pain, it is natural to act on a sensitive nerve; but it is, however, a mistake to think that there is a better chance of cure in a case of epileptiform neuralgia, to stretch a sensitive rather than a motor nerve. In that affection I have ascertained that in keeping the muscles absolutely motionless, by a considerable pressure on them, the attacks aborted completely; and there are many facts which I published long ago establishing that (as, for instance, in the pains that distension of the sphincter and gives rise to in cases of anal fissure), muscles which tend powerfully to contract are the source of a very painful irritation of their sensitive nerves. It would be quite rational from my experiments and from many clinical facts (in several kinds of painful spasms of limbs as well as of the sphincter ani) to divide either the tendon or the body of the muscles seized with painful spasms in the epileptiform neuralgia, or, at least, to divide the trunk or some branches of the facial nerve (after stretching the trunk). As regards the degree of stretching in cases of facial twitching (painful or not), it ought to be such as to alter the structure of the nerve. This rule applies also to cases of neuralgia. Mere stretching is sufficient in that respect, and the process of squeezing, crushing of the stretched nerve, employed by Baum, ought to be rejected as worse than useless, as it can produce neuritis. It has been recommended in cases of stretching against sciatica to draw enough on the nerve to lift the limb from the operating table. Mr. J. Chiene¹ has perhaps justly denied the necessity of doing so. Still it is important to pull strongly enough (in cases of simple neuralgia) to produce at least a considerable diminution of sensibility, persisting for some weeks. The amount of force must be somewhat less in tetanus and locomotor ataxy.²

(C. E. BROWN-SÉQUARD, M.D.)

¹ *The Lancet*, London, 1878, vol. i. p. 904.

² In a good review of the whole subject of nerve-stretching, Messrs. Artaud and Gilson (*Revue de Chirurgie*, Paris, 10 Mars, 1882, No. 3, p. 221) give a detailed statistical account of all the cases they know of that operation. Their statistics can be summed up as follows: 1st, against neuralgia, 70 cases, out of which 48 were quite successful, 10 partly so, 6 were quite unsuccessful, and 6 were not sufficiently reported; 2nd, against contracture, 4 cases, of which 2 successful, 1 partly so, and 1 proved a failure; 3rd, against facial tic (not neuralgic), 5 cases, 4 successful, 1 a failure; 4th, against traumatic spasms and local convulsions, 1 cases, all successful; 5th, against peripheric paralysis, 5 cases, 1 successful, and 4 in which there was an improvement; 6th, against organic affections of the nervous centres, 16 cases, out of which 8 were cases of locomotor ataxy: 5 successful, 3 partly so, and 8 failures; 7th, against tetanus, 28 cases, of which 7 were successful, 10 unsuccessful, and 2 not reported.

LOCOMOTOR ATAXY.

ALTHOUGH locomotor ataxy comes more frequently under the care of the physician than the surgeon, yet in the early part of its course the symptoms are so equivocal, and so liable to be mistaken for those which belong to certain surgical diseases, that, for the sake of the differential diagnosis alone, a short description of this malady should have a place in every system of Surgery.

The symptoms observed in different cases on record are the following:—Strabismus, diplopia, amblyopia, amaurosis, ptosis, contraction of both pupils or only of one; shifting pains in different parts of the body, chiefly in the extremities; cutaneous and muscular anaesthesia and loss of sense of temperature; ataxy, or incoordination of voluntary movements; incontinence of urine and dysuria; loss of electro-muscular contractility in a greater or less degree; occasionally, but rarely, some paralysis of the first, fifth, seventh, eighth, and ninth cerebral nerves: spermatorrhœa, with loss of sexual power and desire; œdematous swelling of the joints, chiefly of the knees; cardiac and gastric disturbance; loss of tendon reflected movement.

All these symptoms are never associated together in any one case of locomotor ataxy; and the variety of ways in which they are grouped constitutes one of the peculiarities of the disease. Thus, to give a few practical examples, the symptoms are grouped in the following way, and made their appearance in the order of time in which they are mentioned.

Case I. Strabismus and diplopia; pains in the legs with numbness of toes; ataxy or unsteadiness of gait; numbness of fingers, followed by pains in the arms and unsteadiness of voluntary movements, or ataxy; incontinence of urine.

Case II. Pains with numbness and heaviness of legs; pains in abdomen and chest; ataxy; pains and numbness in hands and arms followed by ataxy; analgesia; incontinence of urine and dysuria, alternately; hæmorrhoids; loss of sexual power.

Case III. Hæmorrhoids, with pain and numbness in sacrum and perinæum; heavy forcing pains in rectum, with tightness and weight in abdomen. Subsequently pains in legs. Both pupils contracted to size of pin's head, ataxy of movement; loss of taste and smell; impaired sensation and motion on right side of nose; great numbness of feet and legs, and analgesia; numbness of fingers; 'quivering' of muscles; exalted reflex excitability of skin over feet and legs.

In many cases the pains in the limbs are for a period which can vary from a month to ten years or more, the only precursors of the other symptoms with which they are subsequently associated. They consist of two kinds—the one more or less dull, aching or gnawing, and frequently described by the patient as rheumatic; the other, more frequent and characteristic, more acute and lancinating, like electric shocks. The former are more continuous; the latter occur suddenly, in paroxysms which last from a few hours to a few days, and as suddenly disappear for an indefinite period. Even during the paroxysm the pain is not continuous, but intermitting, although it may recur in rapid succession at very short intervals, and may either fix on some particular spot, or fly from one part to another with the rapidity of lightning. The parts which most frequently suffer are the lower and then the upper extremities.

In other instances ocular disturbances are for a long time the only symptoms. These consist of internal or external strabismus, or amblyopia followed by amaurosis. In more than one-half of the cases of locomotor ataxy, paralysis of either the third or the sixth cerebral nerve, with diplopia, occurs during the first stage. It not un-

frequently makes its appearance quite suddenly—in a moment—for instance, on awaking in the morning. Sometimes it continues only for a few days, sometimes for weeks or months, and then disappears as suddenly as it came, to return, perhaps, at some future period. It may occur only at particular times of the day, during certain emotions, or after the eyes have been much fatigued; or it may persist uninterruptedly from the beginning to the end of the disease. Occasionally the strabismus is double, but more frequently it is limited to one eye. In other cases there is diplopia without a perceptible strabismus, when the patient looks in some particular direction. Not unfrequently there is also more or less ptosis and dilatation of the pupil. Sometimes one pupil is dilated while the other is contracted; and sometimes both pupils are reduced to a very small size, without any other ocular disturbance.

Amblyopia is occasionally one of the earliest symptoms of locomotor ataxy. It rarely disappears, or even remains stationary, but generally increases at a variable rate, and often terminates in amaurosis.

The ataxy, incoordination, or loss of power to control the voluntary movements, is an invariable and essential symptom. Occasionally it is first in the train of symptoms, but generally it is preceded, either by the peculiar shifting pains, or the ocular disturbances already mentioned. The disorderly movements occur under two different forms. First, they are generally manifested in the lower extremities, as simple unsteadiness of gait; the patient staggers or totters more or less, like a person partly intoxicated. At the same time he frequently complains of heaviness about the legs, of fatigue after walking a short distance, and particularly after standing. When he stands with his feet close together and his eyes closed, he sways about and would certainly fall if he were not supported. Before the disorder is far advanced, he may be able to walk alone while looking straight before him, or sideways on surrounding objects; but, at a later period, he cannot move without looking at his feet.

When the disorderly movement extends to the upper extremities, the patient is unable to dress himself, or button his clothes, to write, pick up a pin, or reach an aim with his hands when his eyes are closed.

As the disease advances, another kind of disorderly movement supervenes. This is of a jerking character, and arises from spasm of the muscles, which the will puts in motion, but is unable to control; for the patient has lost the power of regulating the degree of their contraction. Once excited by the will, the muscles contract spasmodically beyond the degree intended, and flex or extend the limb with a sudden and uncontrollable jerk.

These two kinds of incoordination are associated together in different degrees in different individuals; but the first kind is that which generally prevails in the early stages of the disease. At a later period, the second or spasmodic kind of disorder increases. All the voluntary movements are more or less hurried and precipitate. The patient seems to be walking upon springs; he proceeds with a kind of prancing gait, and brings his heels to the ground with a kind of kick. If he attempts to take hold of an object with his hands, he will probably thrust it from him by a spasmodic jerk of the arm.

The motor ataxy is usually accompanied, and occasionally preceded, by cutaneous *anæsthesia*, to a variable degree and extent. The fingers, toes, arms, and legs are the parts chiefly affected. Sometimes he can scarcely feel that he has any feet at all, or seems to be 'walking on air,' or 'on his ankle-joints,' or 'on his hip-joints,' when the numbness extends up the thighs.

Analgesia, or loss of sensibility to pain, is frequently experienced to a variable degree and extent; or painful impressions are conveyed to the sensorium with unusual slowness. In several cases seen by the writers, two, three, or four minutes elapsed before the patient experienced any sensation of pain in the part that had been pricked; and, in another, seen by Dr. Clarke, it was not till after the very long interval of twenty minutes that the patient, without being asked, complained of smarting in the part which had been pricked with a needle.

Like the strabismus, the disorders of the urinary organs are remarkable for the intermittence of their attacks. The dysuria and incontinence of urine frequently recur alternately at the same period of the disease.

Spermatorrhœa, followed by loss of sexual power, with or without loss of sexual desire, are among the early symptoms of the malady in a large majority of patients.

A valuable diagnostic feature of locomotor ataxy has been discovered by Professor Westphal. It is the loss of reaction in the leg when a blow is given on the tendon just under the patella.

Occasionally a very remarkable affection has been observed in the course of locomotor ataxy. This was first described by Dr. Charcot of Paris. The knee-joint is by far the most frequent seat of the disease, which occurs suddenly as an elastic oedematous swelling. The part is neither red nor painful, nor is there any constitutional disturbance or fever. Like the strabismus and urinary affections, it may last only a short time, or be prolonged and give rise to permanent deformities. In the latter case the bones and cartilages of the joint have been found diseased.

At an early period of the disease, before ataxy has made its appearance, the differential diagnosis may be exceedingly difficult. But whenever the peculiar flying pains suddenly attack an otherwise healthy person, there is danger of ataxy. If there is strabismus, it is accompanied by amblyopia; and when it is single, the amblyopia is on the corresponding side.¹ Even in cases in which other symptoms have been present, and in which the diagnosis was by no means difficult, operations have needlessly been performed on the eye by surgeons who were ignorant about this affection. It has often been mistaken for incomplete paraplegia.

Pathological anatomy.—In this disease the spinal cord is always altered in structure, and in one particular part. The alteration consists chiefly of a peculiar grey degeneration and disintegration of certain parts of the posterior columns, and secondarily of the posterior roots of the spinal nerves, of the posterior grey substance or cornua, and sometimes of the cerebral nerves. Pierret and Charcot² have shown that the part which is the real seat of the disease is the lateral band of the posterior columns close by the posterior cornua. Generally the posterior columns retain their normal shape and size, in consequence of hypertrophy of the connective tissue which replaces the lost fibres. Corpora amylacea and oil-globules of different sizes are also usually abundant. It is very common to find disintegration of the extremities of the posterior cornua, and sometimes Dr. L. Clarke has found the same kind of alteration in the more central parts of the grey substance. In the latter case the disease is of a mixed nature, partaking of the characters of locomotor ataxy and ordinary spinal paralysis.

Prognosis and treatment.—The prognosis is generally very unfavourable. It is chiefly at the first invasion of the disease that any marked benefit is to be expected from the use of remedies. Hence the importance of an early diagnosis. One of the chief objects is to protect the patient from cold and damp, and place him in an equable temperature. A good and wholesome diet, with wine or beer, is generally necessary. With regard to drugs, nitrate of silver sometimes exercises a very favourable influence on the disease. It may not only alleviate the pains, but diminish the incoordination. It should be first given in doses of one-eighth of a grain, gradually increased to one grain, three times a day, after meals. To prevent it from irritating the bowels or the bladder, it may be combined with opium, with cannabis indica, or with belladonna. For relieving the severity of the limb-pains, which so frequently disturb the patient's rest, there is nothing so efficacious as the subcutaneous injection of morphia (from one-sixth to one-half of a grain) together with atropia (from one-sixtieth to one-

¹ Dr. Hughlings Jackson states that the amaurosis of ataxy, as regards its ophthalmoscopic appearance, is unlike the amaurosis from disease of parts within the head. In amaurosis from intracranial disease the optic disc always shows evidences of recent or past neuritis, which is not the case in ataxy.—*Lancet*, January 10, 1866.

² Charcot, *Lectures on Diseases of the Nervous System*, Second series. *The New Sydenham Society*. London, 1881, p. 21 et seq.

thirty-fifth of a grain). These pains are aggravated by constipation, which, of course, must carefully be fought against. Dry-cupping along the spine sometimes affords decided relief. Sulphur baths have occasionally been of some service. Faradisation has generally been found to be rather injurious than beneficial, but the constant galvanic current has been used with the best results. The positive pole must be applied on the cervical part of the spine and the negative on the lower limbs or on the coccyx. A very powerful irritation of the skin of the lower limbs by a circular blister has proved successful in stopping the progress of the disease, and has sometimes done more. There is also some good to be expected from the use of atropia and the ergot of rye internally, and from slight applications of a white-hot iron on the limbs. As regards nerve-stretching we refer to the special article relating to that means of treatment.

ORTHOPÆDIC SURGERY.

THE pathological nature of the affections relievable by surgical orthopædic treatment is various. They consist mainly of alterations, in form and movement, of the articulations belonging to the head, spine, and the lower and upper extremities. They spring—

1. From congenital influences, the varieties of club-foot, for example; malformations.
2. From influences acting during abnormal parturition.
3. From rachitis and allied constitutional states.
4. From derangement of the cerebro-spinal system, leading to paralysis or *spasm* and contraction.
5. From accidental injuries of articulations, undue pressure and strain; inflammation of joints or contiguous parts, whether or not succeeded by suppuration and its consequences.

Orthopædic surgery comprehends, therefore, a multitude of abnormal forms of the muscular, ligamentous, and osseous systems, of which some are treated elsewhere in this work. On the pathology of deformities arising from diseases of the joints, the reader is referred to the essay on those diseases; strabismus, at p. 124; malformations, with the SURGERY OF CHILDHOOD; burn contractures, under PLASTIC SURGERY, &c. The affections which we have here to consider are principally those which can be remedied by tenotomy or osteotomy, by gradual mechanical extension, by sudden extension during anaesthesia, or by any or all of these means combined.

Before proceeding with the description of the individual distortions and their treatment, it will be well to consider the circumstances which give rise to contraction and deformity, and to inquire into the condition of the muscles, tendons, and bones which may render their division necessary. It is now a well-understood law of pathology, that if any part of the body, into the composition of which muscles enter, be maintained in a state of absolute repose, or be habitually kept in one position, so that the origins and insertions of particular muscles are constantly approximated, whilst the points of origin and insertion of other muscles are consequently proportionately separated, a shortened, contracted condition of the first set of muscles, and an elongated, weakened state of the second set of muscles, are produced. This is illustrated by what occurs during a simple fracture or other injury of an extremity. If the elbow, for example, be for any reason retained a few weeks in the bent position, the muscles on the flexed side of the member become stiff and contracted, and are only gradually restored to their natural mobility by active and passive exercises and use, whilst the stretched-out and weakened extensor muscles recover more slowly their full power of extending the implicated articulation. The state of things just described is aggravated when inflammation, exudation, suppuration, loss of cutaneous or more deeply situated tissues, and consequent adhesions and cicatrices, interpose pain and physical obstruction to the restoration of complete mobility the greater duration of the disorder increases the probability that persevering or active remedial means will be required to obviate the shortening of one set of structures and the elongation and weakening of the opposite set. This shortening and contraction occur more rapidly during the earlier years of life.

The influence of paralysis in producing contracture varies according to the nature and extent of the seizure. A single muscle, as the sterno-cleido-mastoideus, the

tibialis anticus, or the external rectus of the eye, may be more or less completely paralysed; and the antagonist sterno-mastoid, the gastrocnemius, the peronei, or the adductor oculi, may become contracted. Or several muscles habitually associated in their actions may lose their power of voluntary contraction, as the extensors of the wrist and fingers; and the opposing muscles also habitually associated in their actions, viz. the flexors of the wrist and fingers, become relatively shortened.

Few paralyse occur without some degree of contraction ensuing as a consequence, either directly from the impairment of the balance of muscular activity, or from forced repose or maintenance of the part in a particular position.

The induction by abrupt spasm of a more or less rigid, more or less permanently contracted state of a part, is obvious and easily intelligible; but the spasm which produces many persistent deformities is not always of that active, prompt, or tonic kind which is illustrated by certain cases of non-congenital wry-neck and club-foot, but is usually more slow and progressive, as seen in many children's cases of foot-deformity. The contraction in congenital club-foot, and in the majority of congenital distortions can, we believe, be assigned only to a preternaturally excitable or tonic condition of the muscular fibres of the shortened muscles.

In many cases even when the shortened muscle has been set free by tenotomy, the morbidly excitable retractile disposition of the muscle often shows itself again after reunion of the divided part, and the cessation of employment of the mechanical or other means by which the affected muscle had been kept in an elongated state.

This contraction of certain muscles in congenital club-foot is therefore very different from the active powerful retraction which occurs in certain comparatively sudden non-congenital cases, and in which the will of the individual is powerless to effect an improved condition of the limb. In congenital club-foot, and in analogous gradual non-congenital talipes in which paralysis does not exist, if the child is old enough to exercise volition, the affected muscles may be subservient to the will, although volition is incapable of willing entire relaxation of the contracted muscles. Thus the contraction in non-congenital non-paralytic talipes, the early stage of which we are able to watch, throws light on the congenital affection, the early stage of which is hidden in the uterus. In non-congenital cases of months' or years' duration, induced by cerebro-spinal affection or by reflex (?) disorder, the vital abnormal spastic contraction co-exists after a time with secondary accommodation or adaptive structural change. We sometimes, however, before structural change has taken place, have an opportunity of witnessing that, although the patient walks with the heel, for example, much elevated, yet when he is seated, even with the knee extended, he can voluntarily bend the ankle, contact of the sole with the ground exciting abnormal contraction. Further light is thrown upon the nature of the contraction in congenital club-foot by the observation that, during sleep, even in very young infants, the affected foot can be more readily straightened; also that, like as in certain cases of adult hemiplegia, when the child yawns and stretches out the limbs, the inversion of the foot often disappears. This observation would show, that whilst in the ordinary state of the infant's nascent volition the adductor muscles (the tibiales) overpower the abductors (the peronei) and invert the member, the act of yawning, with its complicated reflex activity of inspiratory muscles, and of associated muscles in the extremities, neutralises the peculiar disturbance of muscular activity on which talipes varus depends.

It seems as if in congenital club-foot and analogous distortions a stimulus or irritant were present in the medulla spinalis, acting upon certain ganglionic cells there, which keeps the affected muscle in a state of tonic contraction, yet not sufficient to neutralise the stimulus of the will within the limits of movement permitted by the structural shortening of the member. Many non-congenital spastic contractions appear allied to the condition which prevails in some states of chorea, in which, when the will would permit or cause contraction or relaxation of a particular muscle, an involuntary influence excites contraction, interferes with, and frustrates the voluntary effort. In more intense spasmodic contractions the will is entirely overpowered before structural shortening supervenes to effect the same end.

Secondary changes.—From whichever of the above causes a constantly contracted state of an articulation or limb may have proceeded, the state of things consisting of the inability of the individual to put the part, by the action of the will, through all its proper movements is called a deformity. But if the patient by means of his own hands, or if the surgeon, can overcome the contraction, and put the affected part through its proper movements, no deformity is in reality seen to exist. Positive deformity may early exist, when original disease of the joint has, besides producing contraction, ended in more or less considerable alteration in form and structure of the articulation. But almost equally serious (secondary) deformity may ensue through the influence of the now ill-regulated muscles of the joint, especially when these act upon tissues impaired by disease—the production of sub-luxation, for example. In the lower extremity, the effects of the weight of the body being borne upon the member in improper directions is a very important cause of secondary deformity, adding greatly to the obstacles to restoration. Thus a not severe case of congenital club-foot, remediable in point of form in a few weeks before walking has commenced, may subsequently require treatment of months or of years; or, from the deteriorating cause above mentioned, be rendered irremediable.

We may now pass to the consideration of the means employed in orthopædic surgery for the rectification of deformities. This department of practice avails itself of much that is common with general medicine and surgery.¹ Special orthopædic means are, the relieving of the shortened parts by the employment of mechanical instruments, or mechanical power exerted by the hands of the surgeon or assistants, sometimes with the aid of the benumbing influence of chloroform, and by division of one or more of the contracted muscles, tendons, fasciæ, and bones.

Tenotomy, myotomy.—In this operation the necessary relaxation of muscular resistance, and of accompanying structural shortening, is effected by severing the muscle almost invariably at its tendinous portion. The principles laid down by Delpech for the performance of this operation are followed in the present day. It is remarkable that Delpech never carried out his own principles.² Astley Cooper,³ speaking of palm and finger contraction, states that he divided the contracted bands 'with a pointed bistoury, introduced through a very small wound in the integument. The finger is extended, and a splint applied to preserve it in the straight position.' Here we have essentially the subcutaneous method of operation unequivocally enunciated by that distinguished surgeon. Stromeyer took up the matter where Cooper and Delpech left it, and first applied it to the Achilles tendon (1831), and by his labours and writings caused its diffusion throughout Europe and America. Many alterations in the mode of applying these principles have been made since the original labours of Delpech and Stromeyer. Various knives for severing tendons (tenotomes), and a great variety of mechanical extension apparatus, have been devised. In this place only the means in most general use in this country will be described.

In describing the several distortions no nosological order will be adopted. We will commence with congenital club-foot (*talipes varus congenitus*), because it is one of the most common distortions which the surgeon has to treat, and because it has formed the basis of extensive pathological and therapeutical research, and will best illustrate the principles upon which the management of other distortions should be conducted.

Congenital Club-foot (Talipes varus congenitus).

We may state at the outset, in order to avoid the confusion introduced by late writers, that we employ the words congenital varus to signify the distortion which has from the earliest times been designated varus, or club-foot, the term equinovarus having been subsequently introduced to designate the non-congenital combination of equinus with varus. Some moderns, without prefixing congenital or

¹ Constitutional, medicinal, and dietetic treatment, exercises, gymnastics, inunctions, &c.

³ On *Dislocations and Fractures of the Joints*, 6th edition, 1820, p. 470.

non-congenital, as the case may be, have termed both of these distortions equino-varus. It is true, as we have always stated, that both the congenital and non-congenital forms are compounded of varus and equinus, but it is almost as desirable in practice to adhere to the word varus in surgery as to the word calomel in *Materia Medica*.

Anatomy of club-foot.—Former opinions on the anatomy of club-foot may be advantageously passed over.¹ In 1837, and subsequently, the author laid down the essential characters of the anatomy of club-foot.² The subject has since been carefully and successfully studied by Mr. William Adams.³ The general result of observations of this matter is the confirmation of the opinions emitted by the author in 1837 and 1839,⁴ that club-foot consists of a three fold alteration of the form and position of the foot, the heel being elevated, the toes turned in, and the internal margin of the foot raised from the ground, owing to abnormal action and shortening of the principal, if not of all, the muscles of the inner and back part of the leg. In at least the severer forms, those in which the sole is much contracted, the plantar muscles participate in the primary affection. The ligaments, fasciæ, and integuments on the contracted side of the member are also shortened, whilst the similar tissues on the opposite side are elongated and weakened. These passive tissues follow the fortunes of the active organs—the muscles, on which they are in the main dependent; and become thus secondarily affected. The bones, before and after ossification, suffer in proportion to the intensity of the muscular contraction, and probably in proportion to the earliness of the period of uterine existence at which the distortion commenced; and especially in proportion to the period that elapses after birth, during which the passive osseous structures remain at the mercy of the active muscular agents. The bones further suffer as age advances, by bearing the weight of the body in an improper direction.

The departure from the normal form and relation of bones may be divided into—

1. Primary.

a. The changes especially affecting the tibio-tarsal joint.

b. The change of relation of the anterior bones of the tarsus, as regards the astragalus and os calcis.

2. Secondary, or those induced after birth, by spontaneous aggravation of the deformity, and by pressure upon the parts through walking in an improper manner.

The anatomical changes of bones in varus of practical moment are due to the state of extension of the os calcis, taking with it the astragalus, through which the posterior extremity of the os calcis is more or less closely approximated to the posterior surface of the ankle-joint; and the anterior portions of the articulating surfaces of the trochlea of the astragalus are projected from the ankle-joint in front. Owing also to the forced inversion of the entire front of the foot, the external malleolus is thrown backwards towards the posterior tuberosity of the os calcis, and the anterior extremity of the astragalus slightly inclines towards the inner margin of the foot. The forced elevation of the posterior part of the foot (calcaneum and astragalus) is common to talipes varus and to talipes equinus; but the characteristic peculiarity of varus is the displacement of the remaining bones of the tarsus inwardly to the extent that the navicular bone quits the astragalus, often touching the internal malleolus, with which it frequently acquires a new articulating surface. The cuneiform and cuboid bones accompany the navicular. Moreover, in severe cases the cuneiform, cuboid, and metatarsals, with the phalanges, are drawn backwards, limiting the space of the plantar region.

The changes of bones induced by improper walking, improper pressure and

¹ See *On the Deformities of the Human Frame*, by W. J. Little, pp. 271 *et seq.* London, 1853.

³ *Medical Times and Gazette*, 1852; *Transactions of Path. Soc.*, 1856.

⁴ *Treatise on Club-foot and analogous Distortions.* London, 1839. A large number of treatises on club-foot have appeared since 1837, few of which contain any fundamental researches into the anatomy of varus.

bearing against the ground, by which also sometimes inflammation and ulceration of soft parts are occasioned, do not properly belong to simple uncomplicated club-foot. Only when these injuries are considerable do they affect the results of treatment.

The shortening of the ligaments, fasciæ, and integuments on the posterior and internal aspects of the member may be observed when, before or after operation, attempts are made with the hand to rectify the deformity. In severe cases, much resistance to cure is offered by the posterior ligament of the ankle, the deltoid, the calcaneo-scapoid, the superficial and deep plantar ligaments. The share of resistance offered by the deltoid, for example, is well shown when dissecting severe infantile varus. The author, following Mackeever, has observed that when the deltoid ligament is severed and the navicular bone is liberated, a marked facility of replacement is evinced.¹

FIG. 15.—Severe adult congenital Varus, viewed from the front and inside.

a the tibia, cut down in order to show the relatively posterior situation of the fibula; *b*, the externa malleolus; *c*, the navila; *d*, the posterior extremity of the os calcis shown abnormally inwards; *e*, the astragalus, unduly prominent on the dorsum of the foot; *f*, the navicular bone in contact with the internal malleolus; *g*, the cuboid, its proper superior surface applied to the ground.

The general direction of the structures involved in the distortion is much altered. Thus, the leg-bones are often inwardly rotated from the knee-joint. The surgeon should not expect to find the tendons occupying their normal relations. Those passing over the front of the ankle joint are deflected inwardly, whilst the posterior tibial tendon is deeply situated, owing to the incurvation, and to the backward dragging, and elevation of the anterior part of the foot.

Ætiology of congenital club-foot.—The primary cause of talipes varus congenitus has been already touched upon, p. 228. It consists in contraction of certain muscles, apt to be accompanied or followed by structural shortening,² and by fibrous and adipose degeneration of them.³ Until the researches of Rudolphi, it was held that club-foot, as well as other distortions and malformations, were the consequence of some 'occult influences,' *lusus naturæ*, maternal imagination, and intra-uterine pressure. An occasional effort is made to revive the last of these theories, that of intra-uterine pressure. It has been elsewhere shown⁴ that accidental mechanical causes do sometimes act upon the fœtus, giving rise to easily recognisable conditions, *e.g.* fissures, clefts, intra-uterine fractures, amputations of members from constriction by abnormal bands or by the umbilical cord; and sometimes the co-operation of pressure by the uterine walls and pelvic bones may be surmised.

⁴ *On Deformities of the Human Frame*, pp. 250-314.

Further arguments in favour of the belief that ordinary congenital club-foot is caused by some derangement of the cerebrospinal centres and dependent nerves, as opposed to the theory of its dependence upon primordial malformation or upon pressure of the walls of the uterus, may be thus stated :

Club-foot often co-exists with evident derangement of the nervous centres, as in acephalous, hemiccephalous, and spina-bifida subjects.

Club-foot occasionally co-exists with an analogous distortion of the upper extremity, club-hand, in which the muscles contracted are the anatomical analogues of the parts contracted in the lower limbs. Now if it be admitted that the external configuration of double club-foot may suggest to the unphysiological and unpathological observer, the idea of one of the feet having overlapped the other in such manner that the uterus, *supposing* the liquor amnii to be deficient, has compressed the two feet into the form in which we see them, this explanation does not apply to the club-hands, which bear no such form as can be reasonably attributed to pressure of the uterine walls. Moreover club-foot often exists in one foot only, and the uterine-pressure theory does not explain why one foot escapes. This theory is still less applicable to the highest grade of club-foot, in which the great toe is more approximated to the inside of the leg than pressure of the uterus will explain; whilst the opinion of disturbed action of the muscles before the articulating ends of bones can restrict their action, affords an intelligible explanation.¹

Club-foot is met with in fetuses before the fourth or fifth month of gestation, at which period the liquor amnii is relatively so large as to exclude the idea of uterine pressure consequent upon *supposed* deficiency of that fluid.

We have traced congenital club foot on the paternal side even through four generations, the male infant—the father, the grandfather, and the great-grandfather. If it can be plausibly maintained that club-foot is due to the influence of uterine pressure, deficiency of liquor amnii, pressure of pelvic bones, and its repetition through successive generations, this influence could only be propagated through the female side. We cannot admit uterine influence in hereditary propagation of varus through an uninterrupted succession of male parents.

A comparison of club-foot with the distortions which occur after birth, unmissably from diseases of the nervous system, tends to prove that congenital and non-congenital club-foot spring from analogous causes. Distortion after birth, from altered innervation of muscles, is more common in the lower extremities, and especially in the feet, than in any other part of the frame. Club-foot is also the most common distortion before birth. After birth, talipes varus, in consequence of cerebrospinal affection, is more common than talipes valgus; before birth also, varus is more common than valgus. After birth, foot-deformity, from disease of the nervous system, attains oftener a higher grade on the left than on the right side. This is equally the case with congenital club-foot. Some other agency than accidental uterine or pelvic pressure is required to account for these analogies; they cannot be regarded as mere coincidences.

Grades of congenital talipes varus.—It is convenient for practical purposes to divide congenital club-foot into three degrees of severity: the slightest, that in which the position of the front of the foot when inverted is such that the angle formed by it with the inside of the leg is greater than a right angle, and in which the contraction is so moderate that the toes can easily be brought temporarily by the hand of the surgeon into a straight line with the leg, and the heel be depressed to the natural position. The second class includes those in which the inversion of the foot and elevation of the heel appear the same or little greater than in those of the first class, but in which no reasonable effort of the surgeon's hands will temporarily extinguish the contraction and deformity. The third class comprises those in which the contraction of soft parts and displacement of hard parts reach the highest degree, so that the inner margin of the foot is situated at an acute angle with the inside of the leg, sometimes is even almost in contact with it.

¹ See *Trans. of the International Congress*, London, 1881. Little, vol. ii. p. 412.

Cases of the first and second grades may be respectively converted into the second and third grades by delay in the application of remedies, and by the effects of improper treatment.

FIG. 10. —Congenital infantile Talipes Varus, of medium severity. Reproduced from *Club-foot and analogous Distortions*, 1839.

Treatment.—The indications are to overcome the shortening of the muscles, ligaments, fasciæ, and integuments on the contracted side of the member; to direct the bones into their proper position, to educate the patient's voluntary use of the parts;

FIG. 17. Most severe grade of infantile congenital T. Varus. The great toes of this patient frequently touched the inside of the leg. The woodcut was taken from a plaster of Paris model. The weight of the plaster which was allowed to intrude between the toes and the legs kept these parts asunder, in order to show the extent to which the distortion was diminished when the surgeon attempted gently with his hand to restore the natural form. Reproduced from *Deformities*, 1853.

to give strength to the muscles and ligaments on the elongated side of the member, and to combat the tendency to relapse.

A few slight cases may from the day of birth almost be relinquished to the rubbings and manipulations of the nurse; some require to be lightly bandaged on a strip of tin or firmer metal, bent to a right angle, and properly padded, others require support not only beneath the sole, and against the back of the leg, as when a simple bent strip of metal is employed, but need lateral support or pressure against the internal margin of the foot, as by the application of a tin splint. In the use of this and similar contrivances to be found at the different surgical instrument-makers, the essential point consists in applying the smallest amount of pressure compatible with maintaining the apparatus on the limb, not endeavouring at once either to force the part straight or even to make the tender infantile foot accurately fit the apparatus, but rather, if the apparatus selected admits of adaption, to adjust it to the foot in a somewhat improved position. Practitioners unacquainted with the details of

FIG 18 represents a case of congenital Varus being gradually conducted to a state of equinus

The dotted outline *a*, represents the extreme degree of inversion and elevation of the internal margin to which the foot is occasionally drawn by the anterior and posterior tibial muscles, the position at *b* represents the ordinary quiescent condition, *c*, the position to which a slight touch of the surgeon's hand brings it, *d d*, represents a flexible metal, padded splint bent almost to the shape of the foot as represented at *c* applied along the outer side of the leg and as near as can be along the outer margin of the foot intended to be secured in position by a gently applied roller bandage

management of these cases are surprised to discover how small an amount of pressure suffices in young infants rapidly to improve the form and flexibility. The splint should daily once, or oftener, be removed to ascertain that undue pressure has not been used, to replace it when loosened by the movements of the child, and to improve the position as often as practicable. No unnecessary loss of time should be permitted during this process, as at first the foot rapidly relapses to its most distorted condition. After the part has been straightened, the parent or nurse should be taught to remove the splint and effect gentle manipulations two or three times daily.

If at the expiration of the fourth week distinct contraction of the tendons remain perceptible in spite of the assiduous efforts to overcome the deformity by manipulation, frictions, and steady but gentle employment of splint and bandage, or if

benefit proportionate to the attention bestowed be not realised, or if the case unequivocally belongs to the second or third degrees of varus, the aid of tenotomy will be required to effect restoration. If the surgeon should entertain doubt whether the time for operation have arrived, he may be determined by the observation whether, on holding the foot in the normal position, it springs vigorously back into the abnormal one as soon as the pressure of the hands is removed. In unequivocal cases of the second and third degrees he may, in most cases, decide affirmatively at the moment of birth on the absolute necessity of future operation; and when operation is indispensable, the earlier the period at which it is performed the better. Mr. Stromeyer Little has operated within twenty-four hours after birth with rapid and permanent success. Our practice of late years has been to operate as soon as convenient during 'the month.' The surgeon, when deciding on the necessity of operation, must not be guided solely by the external configuration, but by the amount of firm resistance opposed to restoration by the depth of the furrows existing in the sole and behind and above the heel, and by the degree of tension of the integuments about the internal malleolus. The deep clefts or furrows in question denote intensity of contraction of muscles, and closer adhesion than usual of integuments and fasciæ to the subjacent soft structures and bones. They probably denote also that the deformity dates from an early period of uterine existence. Even atrophy, the usual concomitant of contractions of long duration, is already present in severe club-foot of new-born children, and is a measure of the length of time the muscles have been contracted and exposed to structural shortening and possible degeneration.

The principles of treatment of congenital club-foot are here summarised.

1. Whether the case promises favourably for mechanical treatment only, or needs, as the majority of cases do need, operative interference, commence the treatment *as soon after birth as practicable*.

2. Completely reduce the distortion from the state of a compound one (varus) to the simpler form (equinus), by first curing the inversion of the foot, and the tendency to involution of the sole.

3. Avoid the slightest undue pressure upon prominent points of the leg and foot, by careful padding of the hollow parts, and by using only gentle pressure with any bandage. Avoid obstruction of the returning blood from the limb.

4. Remove splint and bandage daily, practise gentle movements of the foot in the desired direction, endeavour to prevent the part remaining for an instant unsupported and liable to fall back into the deformed position, until it is found that the foot, on removal of the bandage, retains a perfectly good position and flexibility.

5. Never permit the child to be placed on the feet, or to walk until the form and the range of movement are complete, whatever may be the age of the patient.

Be convinced that by carefully following these recommendations, the healthy child will, before the age of thirteen or sixteen months, stand and walk without instrumental aid; that the muscles of the leg will be fairly developed, and a bystander have difficulty in discovering that any distortion formerly existed.

Nature of the operation.—The essential character of congenital talipes varus being a state of abnormal elevation of the heel, and inversion of the front part of the foot by undue muscular contraction, the operative interference required consists of the division of the tendons of those muscles which are mainly, if not exclusively, concerned in the production of the deformity, viz., the tendons of the anterior and posterior tibials and the tendo Achillis. In average cases these three tendons may be divided at one operation. In severer cases the operation should invariably be divided into two parts, the first consisting of the section of those structures which contribute to the inversion—the tibiales tendons; and where the sole is much contracted with a strong prominent band felt at the inner edge of the plantar fascia, that band may be included in this portion of the operation. The division of the plantar textures and elongation of the sole may in severe cases advantageously precede the section of other structures. The tendo Achillis may in such cases be severed in three or four weeks; in adults two or four months later; the inversion having, in the interval,

been overcome. The value of this proceeding, first recommended by the author,¹ consists in the os calcis, when the tendo Achillis is left intact, offering a *point d'appui*, or resisting point, from which the surgeon, during the mechanical after-treatment, is enabled to stretch out and unfold the contracted involuted sole. If this division of the operation into two or three parts is not observed in bad cases, incomplete recovery may result, the sole remain contracted, and the individual walk unduly on the heel and outside the foot, the range of motion of the point of the foot being deficient,—in short, a secondary talipes calcaneo-varus be produced. This secondary deformity is always overcome with difficulty, sometimes it is irremovable. Not unfrequently the patient is left with half or more of the original deformity, requiring that the surgeon recommence the instrumental treatment, devoting himself, as already stated, at first exclusively to the obtainment of eversion of the front of the foot and unfolding of the sole, before he attends to the lowering of the heel.

In a few adolescent and neglected adult cases of congenital equinus and varus, even the peronei may need division, these muscles having become, from protracted duration of the deformity, tensely contracted and considerably shortened.

The following is the mode of dividing some of these tendons, and the instruments which we have introduced as the most appropriate for the purpose. When it is decided in infants a few days old to rectify simultaneously the inversion and elevation of the heel, the operation is more quickly and conveniently done by taking the three tendons in the following order; viz. the posterior tibial, the anterior tibial, and the tendo Achillis. Section of the posterior tibial is best performed by placing the child on a table of convenient height, on its back, inclined towards the limb to be operated on. This should be thoroughly rotated outwardly, resting upon its outer side, whilst a competent nurse holds the child's hands and the opposite leg out of the way of the surgeon. An assistant, having a few small dossils of lint, a bandage, and the necessary knives within reach, takes his place by the side of the patient, and holds the thigh and knee of the limb to be operated on with one hand, being prepared with the other to hold firmly or adduct the foot as may be required. The operator, when about to sever the left posterior tibial, seats himself in front, takes the foot in his left hand, and endeavours to feel the slight prominence of the posterior tibial tendon with the left thumb; during the time he either abducts the foot with the right, to put the tendon on the stretch, or takes advantage, during the spontaneous movements of the infant, to observe where the tendon is thrown into palpable relief.

When, however, the surgeon cannot feel the tendon, it is practically quite sufficient to make out the inner edge of the tibia, about a finger's breadth above the lower end of the inner malleolus; or should there be any difficulty in defining this ridge of bone in consequence of the fatness of the limb, the careful insertion of the knife *exactly midway between the anterior and posterior borders of the leg*, on its inner aspect, will be an exact guide to the position of the tendon, not forgetting, as anatomy teaches us, that an incision made a little in front of this line might wound the internal saphena vein and nerve; and if made behind it would run the risk of dividing the flexor communis digitorum instead of the tibialis posticus; or the knife might even pass posterior to the former tendon, and, if carried deep enough, might wound the artery and nerve without touching any tendon whatever.

Having thus determined the situation of the posterior tibial by one or all of these methods, a sharp-pointed knife is passed through the skin at about a finger's breadth above the inner malleolus, according to the age of the child. It must be made to penetrate steadily down to the tibia, *perpendicularly to the surface*, to a depth varying from a quarter to half an inch. In doing this, it is necessary to be quite sure of sufficiently opening the fascia covering the posterior tibial and common flexor tendons; otherwise, when the probe-pointed knife is passed in (as will be described in the next stage of the operation), it may either hitch against this dense unyielding structure, or glide over its surface behind the deep layer of muscles, instead of passing through the opening in front of them.

¹ *Lancet*, May 25, 1839.

In order, therefore, to accomplish the *free division* of this fascia of the leg close to its insertion into the edge of the tibia, and likewise the proper sheath of the posterior tibial tendon beneath, the sharp-pointed knife should be passed to the depth above recommended; the handle must then be elevated so, as to depress the point of the blade; that is to say, the instrument should be used as a delicate lever, the centre of motion being the skin, which may be pressed upon gently by the back of the knife; and in this way an opening of the requisite size can be made in the fascia at the bottom of the wound, without enlarging the external aperture.

Having thus far accomplished the operation, the sharp-pointed knife is withdrawn, and a probe-pointed one is to be passed into the puncture through the skin, superficial fascia, layer of adipose tissue, deep fascia, and lastly the proper sheath of the tendon, and be now inserted a little further in, so as to get well between the posterior tibial and the tibia. When satisfied from the sensation communicated to the knife that the bone is on one side and the tendon on the other, all that remains to be done is to turn the edge towards the tendon, giving the knife a slight cutting motion, while at the same time the assistant firmly abducts and depresses the inner border of the foot.¹ The surgeon accustomed to tenotomy now commonly effects division of the posterior tibial tendon in very young, even stout, infants with a single sharp pointed convex-edged scalpel, instead of performing the operation *à deux temps*. With the latter operation the surgeon is less likely to divide more than he desires.

As soon as the peculiar jerk of something having suddenly yielded is detected by the assistant, he should immediately relax the foot, and apply a dossil of lint over the wound, holding it there with the forefinger during the division of any other tendons. If, as has happened, the artery is supposed to be cut, either from the escape of florid blood or from the blanched appearance and reduced temperature of the foot; or one of the large superficial or deep-seated veins, indicated by the escape of black blood, it will only be necessary to apply instantly a graduated compress, and to roll with some firmness a bandage upon the foot and ankle. This, however, may require to be loosened if the colour of the toes shows any indication of undue pressure. Under ordinary circumstances, operations are bloodless if the surgeon and assistant be experienced and prompt. The puncture unites within forty-eight or seventy-two hours if the part be kept at rest, and a due temperature maintained. If the operator is not ambidexter, he will find, in the operation for dividing the posterior tibial tendon of the right limb, that he had better stand on the left side of the patient with his back to the patient's face, whilst the assistant sits down in front, and holds the thigh with one hand while he steadies the toes with the other.

Taking, then, the mesial line on the inner aspect of the leg at about three-quarters of an inch above the inner malleolus as the true position of the tendon, the sharp-pointed knife is to be inserted perpendicularly, with its back towards the sole of the foot. It is thus made to divide the skin and deep fascia in the same way as was explained when cutting the left posterior tibial tendon. After this instrument is withdrawn, the probe-pointed knife may now be used to finish the operation, which in all other respects agrees with the section of the corresponding tendon on the opposite side of the body. The long flexor of the toes, owing to its proximity, is often partially or wholly severed at this operation on the posterior tibial.

Weis and Velpeau divide the posterior tibial tendon at its insertion into the navicular bone, the knife being inserted so as to meet the tendon about an inch (in the adult) below and in front of the inner malleolus. This plan is inapplicable to infants. In adolescents and adults this tendon is usually so prominent to the eye and touch above and behind the internal malleolus, that it is an easy matter to sever it by inserting the point of a narrow straight scalpel at the posterior edge of the tendon, directing it forwards between the tendon and tibia, so as to divide it without risk of injury to the posterior tibial artery or the internal saphena vein. It is unnecessary to give particular directions for division of the plantar fascia when

¹ We have seen more than one straight sharp-pointed bistouri caché used instead of two separate knives. The best of these was in the hands of Dr. Dick.

needed, those given respecting operations on other tendons being amply sufficient. The direction of the knife should be from without inwards, *i.e.* from the external margin of the foot towards the internal margin.

Division of all the plantar tissues from without inwards, sometimes with open wound, latterly subcutaneously, from without inwardly has been practised. In this wholesale section, guided by Jules Guérin's experiments on the safety with which subcutaneous sections may be made in animals, the fasciæ, muscles, tendons, nerves, and vessels down to the under surface of the tarsal bones have been severed. Experience shows that this proceeding is not required in adolescents and still less in infants and young children. In most severe adult cases, so great is the difficulty of cure that anything short of mutilation is applicable. In inveterate elderly adult cases restoration to *perfect* form and movement is found impracticable, mutilation in the shape of excision of a considerable wedge of the tarsal bones, or even a Pirogoff operation, may be done in the adult where the sufferer demands riddance from deformity at any price.

The division of the anterior tibial tendon in talipes varus should follow the section of the posterior tibial; the patient being in the same position, and the assistant still holding the limb, and pressing his finger upon the lint covering the puncture already made above the ankle. The operator should feel for the most prominent part of the tendon over the joint, somewhat nearer the malleolus than in the normal foot, and insert a sharp-pointed knife, with its flat surface towards the outer edge of the tendon; and having passed it well beneath, he should turn the sharp edge towards the tendon, whilst the forefinger of the left hand is pressed gently over the part, to warn him of the approach of the knife to the surface. The assistant, who has been steadily abducting the foot during the operation, gradually relaxes his endeavours as he feels the tendon yield; and so soon as he perceives the distinct snap which is the result of its complete division, he should immediately relax his hold, and apply a small do-sil of lint over the puncture.

Division of the tendo Achillis is accomplished after turning the infant over on the abdomen. Whilst an assistant endeavours to bend the ankle, the surgeon introduces a small straight tenotome through the integuments from behind forwards at the side of the tendon. As soon as the point of the instrument is judged to have reached the anterior surface of the tendon, it is passed in front of it; the cutting edge is then directed to the tendon, severing the tense cord by one or two movements of the blade against it, and without wounding the integuments, except by the puncture of entry. The assistant should carefully relax the pressure he may be exercising upon the foot in proportion as he feels the part is cut through.

These operations, when properly done, occupy not more than a few seconds each, and are usually absolutely bloodless. Much has been written concerning the danger of wounding the posterior tibial artery. I have only once witnessed any trouble from the circumstance. This accident occurred to a former colleague. Ligature of the vessel on account of a small filbert-size aneurism was required the third week after the operation. In that instance the wound in the vessel would have probably healed without aneurism if the surgeon had not too soon after the accident incautiously removed the bandage and abducted the foot. When injury of the vessel is suspected or known to have occurred, the removal of the bandage at the commencement of the mechanical after-treatment should be delayed one or two weeks and be proceeded with using extreme gentleness.

A pasteboard or other splint, previously moulded to the form of the contracted part, should be employed immediately after the operation, to ensure quiet, and favour healing of punctures.

Apparatus required after operation.—The metal splints already recommended for cases relievable without operation are equally applicable after division of tendons. Three days after operation, one of these splints, not much straighter than the affected foot, should be selected, or if a splint capable of being adjusted be used, it should be set at an angle or in a direction that the child will bear without complaint. In patients above the age of two or three months, a more elaborate and effective

apparatus may be employed, when the pecuniary circumstances permit it. The woodcut, fig. 19, represents the lightest, the most effective, and the most inexpensive of the more elaborate apparatus constructed for the purpose. The perpendicular lever and the toe-spring are derived from Scarpa's shoe; but as Scarpa's apparatus contains no contrivance for depressing the heel, but relies simply on the effect of the weight of the body acting during locomotion, the author has introduced the movable thumb-screw, capable of being inserted into any required hole of the quadrant shown as above. This is an improvement upon the male and female screw, and the double-acting ratchet-screws often used for the purpose. The simple arrangement of a movable thumb-screw has, in addition to lightness, the advantage of permitting mobility of the ankle in the direction of bending—a circumstance of much importance. No other apparatus which the author has seen possesses the advantages of permitting perfect freedom of motion of the ankle during exercise or as much freedom as the surgeon may consider desirable, and, owing to the action of

FIG. 19.—Dr. Little's Shoe for Varus of the left foot.

a strap to be attached to the buckle *b*, intended to moderate the action of the lever spring *c*; *d*, two straps which start from within the heel piece on the outer side of the foot near the sole piece, and are intended to be secured to buckles on the opposite side of the instrument, for the purpose of holding the posterior part of the foot firmly against the instep of the shoe, whilst the strap *e*, and short spring to which it is attached, draw the front of the foot outwardly. The convalescent may take exercise in this apparatus.

the spring lever, continually disposing the patient to tread on the inner margin of the sole.

Cases of the first grade of infantile deformity are usually rectified in two or three weeks, those of the second grade in about four weeks, and those of the highest grade, the operation and the mechanical treatment having been divided into two or three stages, within two or three months. The treatment of adolescents and curable adults varies from two to twelve months.

Relapse not rarely occurs after the most complete flexion and abduction has been obtained. It takes place insensibly, at all ages, especially when growth is most rapid, and is due to too early discontinuance of instruments, and to neglect of manipulations and of passive and active exercises whilst the foot remained in a good position and the patient was enabled to tread in a natural manner. The worst so-called relapses result from previous incompleteness of operation or of restoration. No case should be considered finally cured until the mental development of the

patient is sufficiently advanced for him to take an interest in his cure, and to be able voluntarily to hold the part in a perfect position, and perform the natural movements of it. In relapsed cases repetition of tenotomy is not commonly required. Often the *tendons* will be found of ample length; sometimes the diminutive belly of the *gastrocnemius*, for example, wasted through want of the stimulus of adequate alternate flexion and extension—*i.e.* proper exercise—being shortened and drawn up towards the popliteal region. A common cause of relapse is doubtless the previous insufficient curative elongation of the *fasciæ*, ligaments, and muscles, situated on the contracted side of the member, and is favoured by the corresponding relaxation and weakness of structures on the opposite side. Continuous gentle re-application of the extending apparatus, aided, as soon as flexion to the right angle is reached, by exercise with a wedge of cork beneath the front of the sole, suffices to restore these cases usually within a few weeks—*i.e.* within the period the patient would have been required to lay up if tenotomy had been repeated. It is satisfactory to be able, not only to spare the patient and friends the concern incidental to any operation, but to be able to avert, by mechanical means only, without loss of time, the discredit which attaches to the repetition of the operation.

Much benefit is derivable from a foot-exercising gymnastic apparatus which a patient above the age of four years can be directed to use for some minutes, or older patients even for some quarter of an hour, two or three times in a day. The accompanying drawing sufficiently explains the necessary proceeding calculated to obtain greater mobility at ankle-joint, and increased alternating elongation and shortening of the flexor and extensor muscles of the foot. The author originally employed Stromeayer's foot-board for this purpose. In the treatment of relapsed adolescents,

FIG. 20.—Exercising apparatus to aid in completing the bending of a resisting ankle-joint, suggested by seeing the application of the same principle in the first Great International Exhibition in 1851, forwarded by Dr. Behrend of Berlin.

an apparatus that will bear the risks of walking exercise, and at the same time favour mobility of the ankle-joint in the required direction, is afforded by fig. 21.

After the operation for club-foot, even in infants, continuous application of splints or other apparatus is required for four or five weeks; in older children, for two or three months. The less severe the case, the more often the apparatus may be removed for cleanliness, and to examine lest undue pressure is employed. It is the boast of successful treatment of club-foot to be able to accomplish this result without a single excoriation. The surgeon should watch that, in his efforts to depress the heel and abduct the foot, the part be not too long maintained in one position, to the extent that the power of lowering the toes and of inverting the foot is lost; or, in other words, a valgus be engendered in exchange for the varus. This secondary valgus has been attributed to the non-union of the severed posterior tibial tendon.

It is really due to too long-continued retention of the foot in an abducting apparatus. We have witnessed it in children born with varus, who had been treated without operation. Its production is favoured by the same constitutional debility which produces spurious valgus, or flat-foot, in rapidly-growing children, who have previously had perfect feet.

Instrumental treatment is further required during at least a portion of each twenty-four hours, until the individual is enabled to plant the entire sole evenly and properly upon the ground, to thoroughly flex and extend the part at will, and

FIG 21.—Dr. Little's double-hinged upright Shoe for severe rigid Varus of left foot

the upright hinged in two places which when applied to the leg adapts itself to any degree of deformity, *b* a spring curved outwardly which when brought into contact with *a* can be then secured by means of a swivel stud, *d* and two straps for purposes similar to straps *d* in figure 19, *e* moderating strap to be secured to *f* as required. If the act of bringing the spring *b* into contact with *a* should occasion too much strain *b* can be fastened at any required distance from *a* by means of a tape. In the application of a varus shoe success depends much upon the malleability with which the sole is applied to the sole plate of the apparatus and upon careful adjustment of the power employed. The foot part of the shoe should be properly applied before the upright lever is secured. The moderating strap is the last to be fastened. The sole should be covered with a thick layer of gutta serena or india rubber.

habitually, when walking properly, to evert the toes. In numerous cases a child requires no apparatus after the age of five or six months, but the majority need some instrumental aid such as leg-irons to evert the entire extremity until the intelligence is sufficiently awakened—say, until the age of three years. The maintenance of the 'cure' depends, as in all diseases, greatly, if not mainly, upon the individual or his natural guardian. We have had cases under observation off and on from infancy to puberty, owing to successive relapses, which have more commonly occurred abroad or in the colonies. We have witnessed examples of adults returning to be re-operated on, who have been successfully referred to their own efforts, with a few instructions as to mechanical attention.

After tenotomy no replacement of the part should be attempted until the puncture has cicatrised. Much has been written respecting the propriety of immediate replacement. It is unnecessary in slight cases, and impossible in severe ones.

In slight cases, nothing is gained by it; for, if the position may be immediately rectified, the part cannot be immediately used. The limb should therefore be gradually replaced while the tendon is consolidating itself.

We have often seen in consultation slight cases in which the Achilles tendon had been, perhaps unnecessarily, divided, or had been divided before the inversion had been sufficiently overcome; the foot had been immediately placed in a fully bent position, and converted into a, probably permanent, talipes calcaneus. Many surgeons have stated that they have never seen any harm from immediate complete fixation of the foot in a fully flexed position. The experience of such surgeons justifying this statement is widely different to that of surgeons who have made this matter a special subject of observation.

The influence, in interfering with union, of too considerable and too early separation of the ends of a severed tendon, and especially of frequent motion, as in walking, is incontestable. Experiments upon animals have proved that considerable lengths of tendon may be excised, and union nevertheless ensue; but the knowledge possessed of the great extent of the powers of the economy is an insufficient reason for neglect of those rules of caution which experience dictates. The immediate separation of a severed tendon to too great an extent should be avoided. Half or three-quarters of an inch may be safely borne, although as a rule gradual separation is preferable. The condition of a severed tendon approaches that of a fractured bone; too great separation of the severed ends, depression of temperature sufficient to suspend active arterial circulation, too early movement of the parts, and inherent vice of constitution, may cause tendon, like bone, to remain imperfectly united.

Stromeyer has suggested, that previously to operation the patient should be accustomed to wear the replacing instrument. This plan is desirable when the practitioner is unfamiliar with the treatment of deformities; for he thereby becomes versed in the action and mode of application of the apparatus, and is rendered certain beforehand of the appropriateness of the contrivance.

With reference to the choice of the apparatus, Stromeyer has rightly remarked, that every practitioner will select that of which he best understands the action and mode of application. This sagacious observation explains also one cause of the zeal with which each writer advocates his particular appliance.

It cannot be too strongly insisted upon, that in a large number of deformities, whether treated with or without operation, expensive instruments are unnecessary. More depends upon the tact, patience, and perseverance of the practitioner than upon the particular apparatus employed. Common roller bandages, with or without starch and plaster of Paris, tin, wood, or gutta-percha splints, aided by manipulations, may, in ingenious hands, supply the place of the most elaborate contrivances.

It may sometimes happen that no instrument is available, and the after-treatment may require to be conducted entirely by manipulations. Thus an adolescent case of double congenital varus was admitted into the London Hospital, under the care of Mr. Oritchett, presenting large ulcers with necrosis on the dorsum of each foot, induced by pressure during the mechanical treatment after tenotomy. As the unhealthy character of the ulcers depended upon want of air and exercise, and the application of suitable instruments was impossible, we recommended not to wait for cicatrization of the ulcers, but to repeat tenotomy, and effect forcible manipulations of the members. Chloroform was upon one occasion employed. By these means the feet were gradually straightened, cicatrization of the ulcers was thereby favoured, and within three months the lad quitted the hospital entirely restored.

After congenital varus, as after acquired deformities, retentive apparatus may be required; these for the most part consist of jointed irons to support the weak articulations, and springs to assist the action of the debilitated muscles. These should be made of steel, or of caoutchouc, after the manner in which Gray, the manufacturer of artificial legs, employed it as a substitute for living muscles.¹

The completeness of recovery in the great majority of the cases of congenital varus constitutes one of the triumphs of surgical art.

¹ This use of india-rubber was brought to the notice of the profession by the author in *Treatise on Deformities*, 1853, p. 36.

During childhood congenital varus may be entirely cured, without other traces of deformity than smallness of the member, greater squareness of the front of the foot, and sometimes less complete mobility of the ankle-joint, the patient recovering entire volition. When the case is unattended to before adult age, the internal margin of the foot may never be completely applied to the ground, owing to the impossibility, in some cases, of perfectly unfolding the os cuboides from its inferior and rotated position in the tarsus; in other instances, owing probably to the round head and neck of the astragalus having become so much inverted in relation to the remainder of the bone, that part of the undue convexity of the tarsus outwards becomes irremediable. Every year reduces the number of adult cases of varus requiring treatment, so that the consideration of any means of meeting the attendant difficulties may appear superfluous. The author has often found an efficient agent in a firm pad placed in the sole beneath the os cuboides, pressure being at the same time made upon the upper surface of the other tarsal bones.

During the last ten years, several surgeons, who it is obvious have had no experience of the success which attends the treatment of congenital varus upon the principles laid down in this work, have resorted to larger surgical operations in children than have been here recommended. These operations have been dictated by the desire to spare the expense of mechanical apparatus, and more effectually to guard against the necessity of attention to prevent relapse, as well as to save time and trouble to the patient and the surgeon. They have even in children and adolescents removed a considerable wedge shaped portion of the tarsal bones, literally severing or almost severing the bony frame of the foot, and removing by a sort of surgical joinery as large a wedge of it as suffices to give the foot a valgoid rather than a varus distortion, and to destroy the natural arch. A third operation consists in freely opening the ankle-joint, removing therefrom the least offending, because the least displaced, of the bones—the astragalus; so that by loosening the connection of the foot with the leg the surgeon can give the form he desires. Another surgeon, in order, it is presumed, to facilitate removal of the astragalus and favour subsequent eversion of the foot, also removes that part of the fibula which constitutes the external malleolus.¹ The public journals have recorded deaths from these operations. The author has examined two of the recovered cases; in them the arch was destroyed, the foot much shortened, a valgoid state having succeeded to varus. The effect of the last of the above operations is to occasion partial ankylosis or loss of movement of the ankle, and as most newly-made joints commonly after a time become ankylosed, this result may be expected to follow this operation. When it is remembered that these operations of tarsal osteotomy have been performed in young children, who might have been cured almost as quickly in the ordinary way without mutilation of limb or danger to health or life, it is unnecessary to say more in deprecation of its employment. To lessen or remove distortion should not be so much the aim of the surgeon as the restoration of the part to a state of integrity, and this can be effected by any painstaking surgeon versed in orthopædy. To restore parts to integrity of form and function by mostly painless division of tendons and gentle gradual replacement, ought not to be considered below the dignity of the surgeon, aided by the right-minded parent and trustworthy nurse.

Congenital Talipes equinus, Talipes equino-varus, Talipes valgus, Talipes equino-valvus, Talipes calcaneo valgus, and Calcaneo-varus.

By talipes equinus is understood morbid contraction of the muscles of the calf, and consequent depression of the toes, the adductors being unaffected. This is a very rare congenital affection. We have met with two cases in the same family—the first born, and the last child, the eleventh. When it has not been treated in infancy, locomotion is effected on the inferior extremities of the metatarsal bones and

¹ Dr. Rupprecht, *Jahresbericht des Gesellschafft für Natur- und Heilkunde, Dresden, 1881* p. 39.

phalanges. In severe cases the internal margin of the foot is slightly inclined inwardly, and the metatarsus is projected forwards. There is not, as in varus, any disposition to tread exclusively on the outside of the fifth metatarsal bone or on the dorsum.

The existence of congenital talipes equinus has been emphatically denied. It is a question of fact and capability of discrimination. It may be suspected that the rare cases of congenital equinus which may have fallen under the observation of those who have denied its existence have been erroneously classed as varus. In congenital contraction of the muscles of the calf, owing to morbid elevation of the heel, the narrow portion only of the trochlea of the astragalus is retained within the malleoli, and the front of the foot falls or is drawn readily either inwardly or outwardly; the more ready or usual direction being inward; just as we see in some sound children there is a preponderance of the adductors (tibiales) over the peronei, and the feet are consequently observed to be turned in more often than out. Consequently the surgeon who makes no allowance for the ordinary tendency of the feet to incline, and who considers a case to be varus when he sees the foot with never so slight an inward inclination, does not believe in the existence of congenital talipes equinus.

FIG. 22.—Congenital Talipes Equinus.

The few cases of unoperated congenital adult equinus which we have seen have remained talipes equinus throughout. The patients have continued to walk on the metatarsal extremity of the great toe, as well as on the little toe.¹ The great toe has never been raised from the ground, as it is in congenital varus. No original or secondary affection of the adductors had drawn the foot in, so as to resemble congenital varus or even non-congenital equino-varus. The patient, we repeat, still walked on the ends of all the metatarsal bones, and especially on those of the great toe and the little toe.

If congenital equinus be rejected upon the ground that must be taken by those who deny its existence, then it may as justly be asserted that neither does non-congenital talipes equinus exist; for there is no non-congenital talipes equinus in which a trace of inversion or of eversion cannot be discovered, which when very marked is termed either talipes equino-varus or talipes equino-valgus.

The discussion as to the existence or non-existence of congenital talipes equinus continues for the same reason that discussion is endless in every department of natural history, as to whether a given object belongs to one species or forms another species;

¹ We have recently examined an adolescent with well-marked hereditary congenital equinus. It was further remarkable by constituting the fifth example of the deformity in living members of the family, viz., the father, two paternal uncles, and one aunt.

one observer recognising a radical difference, which another observer either overlooks or explains away as belonging to another species.

Talipes valgus, equino-valgus, and calcaneo-valgus, whether congenital or acquired, are the terms applied to those distortions which contrast most with talipes varus, or ordinary club-foot. The front of the foot is more or less turned out in each of these varieties, instead of being inverted as in varus. In valgus the peronei are the muscles mainly contracted; in equino-valgus the tendo Achillis is also tense, and the heel elevated, the toes at the same time pointing outwardly. In congenital calcaneo-valgus the heel is depressed through the contraction of the anterior tibial, and the toes pointed outwardly from tension of the peronei. In non-congenital calcaneo-valgus the depressed heel is due primarily to evident paralytic wasting of the calf-muscles.

The foot deformities named respectively equino-varus and equino-valgus are both non-congenital, and offer other points of analogy, the chief of which is their dependence upon either spasmodic or paralytic contraction, as the case may be.

FIG. 23.—Front view of a congenital Talipes Valgus of the right foot of a boy aged four years.

d a, the outer edge of the foot raised from the ground; *e*, the great toe raised from the ground, although the internal edge of the foot is directed towards it; *b*, the internal malleolus; and *c*, the internal extremity of the navicular bone, being the parts upon which the patient walked.

FIG. 24.—Extreme Congenital Calcaneo-Valgus.

The reader, on comparing fig. 25 with fig. 16, will perceive the similarity of form between equino-varus (a non-congenital affection) and congenital varus, and might reasonably conclude that little reason exists, as far as an external form is concerned, for making any distinction between them. An essential difference is, that congenital varus is fully formed at the time of the child's appearance in the world, whereas equino-varus, when it proceeds from paralysis, is gradually produced, slowly attaining the maximum of distortion. In spasmodic equino-varus also the distortion resulting from either obvious or obscure disorder of the nervous system is rarely complete *ab initio*; on the contrary, it is for the most part slowly developed. The analogy of equino-valgus (fig. 26) in some respects with equino-varus is apparent. In both there exists contraction of the tendo Achillis; both are produced after birth from either spasms or paralysis. In equino-valgus the front of the foot is overt, and not inverted as in varus.

The deformed, enlarged, and protuberant heel of talipes-calcaneo-valgus is the consequence of several years' locomotion on the posterior extremity of the os calcis. This bone has in effect, in the fully developed deformity, a nearly vertical instead of the nearly horizontal position which obtains in the well-shaped foot (see fig. 28).

The rules already laid down for judging of the necessity for tenotomy in varus and the number of contracted tendons to be divided, apply to each of the distortions now under consideration. The principles which should direct the mechanical treat-

FIG. 25.—Non-congenital T. Equino-Varus. The arrows indicate the direction of the convexity of the tarsus and metatarsus, forwards and outwards; the perpendicular line through the axis of the limb shows the extent of the inward deviation of the metatarsus, by which the base of the little toe, being brought completely beneath the axis, has to support the entire weight of the body in walking; and is, in consequence of its attrition against the ground, a considerable cause of suffering.

FIG. 26.—Talipes Equino-Valgus, from loss of power in anterior tibials, and consequent contraction of calf muscles, and of peronei:

FIG. 27.—Early stage of Non-congenital Calcaneo-Valgus.

FIG. 28.—Fully developed Non-congenital Calcaneo-Valgus, from paralysis of gastrocnemii and consequent contraction of muscles of the sole, of anterior tibial, and peronei muscles. In some instances the anterior tibial shares the fate of the gastrocnemii.

ment are equally applicable. The experience and ingenuity of the surgeon are required to adapt the apparatus to the peculiarities of each case.

A variety of congenital varus occasionally presents itself, in which the inner margin of the foot is slightly raised, the sole contracted, and the dorsum prominent

towards the outer side of the foot, but without elevation of the heel. In these cases the muscles of the ankle are unaffected. We have designated this affection calcaneo-varus; it is also called plantar-varus. The treatment consists in making pressure by means of a pad upon the prominent dorsum, and in suitable manipulations. A beneficial result is soon observed; but the affection is prone to return. Division of the plantar fascia and of the long flexors of the great toe rarely exercises as much permanent benefit as is expected, because the quantity of plantar textures necessarily left unsevered suffice after cessation of the treatment to reproduce contraction. Moreover, calcaneo-varus does not seriously impair locomotion.

Some irregular congenital foot-distortions are met with. In a few of these we find distinct paralytic loss of muscular power: in one case well-marked paralytic varus, with much atrophy of the soft and hard parts; in another, paralytic contraction of the hips, knees, and feet, with implication of the upper extremity. The only treatment applicable is to relieve contraction by manipulation, friction, and in unyielding cases by tenotomy, thus offering a chance to the muscles which remain partially under the will, to support the individual in attempts to effect imperfect locomotion. We have watched these cases from birth to adolescence, and a few to advanced age; in many the paralysis has remained undiminished. In other instances of contracted limbs from infantile paralysis, the primary disorder is augmented about the time of the grand climacteric.

Distortions originating at the moment of Birth.

We have seen that in the earliest times of the study of congenital distortions, they were successively attributed to the anger of the Deity, *lusus nature*, malposition in, and pressure of, the uterus. In the present day, an enlarged observation of non-congenital as well as congenital distortions leads irrefragably to the conclusion, that the numerous causes which are found to operate in the production of distortion after uterine existence, exercise analogous if not identical effects, whilst the fetus remains within the uterus. These causes are, hereditary and maternal influences, disturbance of the nutritive, respiratory, circulatory, and nervous systems of the fetus and infant, accidents, entanglement by the funis and abnormal bands, intra-uterine fractures, malposition and pressure, fixed repose in one position, and inflammation. In order to illustrate the obnoxiousness to distortion existing at every epoch, we shall here describe a group of distortions, many of which unquestionably take their origin at the period intervening between uterine and independent life, that is, *during* birth. (See classification, p. 227). We believe we can particularise the moment, as that interval which unfortunately in cases of abnormal labour connects the cessation of placental with the beginning of pulmonary respiration. When we reflect upon the important phenomena in the economy at the moment when it should adapt itself to the immense changes involved in the abrupt transfer of the oxygenating process of the blood from the placental to the pulmonary cell surfaces, we should anticipate that any retardation, interruption, or arrest of this transfer of the most important function should be attended with the greatest evil to the system at large, and especially to the most susceptible, the nervous system.

We know that a state of suspended respiration and animation is the common consequence of many of the accidents attendant upon birth; and we might infer, from the evils often witnessed after recovery from the asphyxia of drowning or of choke-damp, what might be the consequences of the apnoea and asphyxia of new-born children. Some of these entirely escaped notice by the profession, until published by the author in the *Lancet* in 1843-4. The lungs suffer in the form of atelectasis; the heart probably in delayed or deficient closure of the foramen ovale, and possibly in straining of its walls; the nervous centres from effusions and apoplexy, followed by impeded developments, atrophy of individual parts, sometimes by impaired intellect and volition, convulsions, and spasmodic contractions.

It is scarcely necessary to add, that difficult and instrumental labours, and those in which the cranial bones and brain, and even the vertebrae and their contents,

have suffered mechanical injury, are more likely to be followed, if not by death, at least by general convulsions and other serious derangement of the nervous system, of which a prominent symptom are the 'internal' or subdued convulsions of the nursery.¹

A common class of affections, resulting from injury at birth, whether the injury be mechanical or vital, consists of a peculiar diminution of volition with tonic rigidity, in varying degrees of a part or of the whole of the muscles of the body, described as 'the spastic rigidity of new-born children.' Both lower extremities are more or less generally involved. Often one limb only is referred to by the parents; but careful examination usually shows a smaller degree of impairment in the limb supposed to be unaffected. In some of these contractions originating at the moment of birth, the cases are of distinct hemiplegic character, the paralysis having passed off during the first year of life, the more or less active spasmodic contraction with structural or adapted shortening remaining (*retraction musculaire* of Guérin). This state of peculiar spastic rigidity of young infants may even continue through the whole duration of life. We have known patients over forty years of age thus affected from birth.

FIG. 20.—Spastic Contraction of Flexors and Adductors of the Lower Extremities (with knock-knees), consequent on Asphyxia Neonatorum. Similar distortion may result from 'convulsions' during teething and other cerebro-spinal affections.

The amount of contraction in the hips, knees, and ankles is often considerable, and the leanness proportionate to the contraction. The flexors and adductors of the thighs, the flexors of the knees, and the posterior muscles of the legs preponderate. The thighs and knees cannot therefore be completely extended, or the heels be applied to the ground. In some cases the upper extremities are held down by the preponderating action of the pectorals, *teres major* and *minor*, and *latissimus dorsi*; the elbows are semi-flexed, the wrists partially flexed and pronated, and the fingers incapable of perfect voluntary direction. Participation of the muscles of the trunk is sometimes shown by the shortened, flattened aspect of the pectoral and abdominal surface, as compared with the more elongated, rounded form of the back. The prominence of the back partially disappears on recumbency; but the greater weakness of the muscles on the dorsal aspect of the trunk is obvious when the individual again

attempts to sit upright. The inability and indisposition to exert the abdominal and other muscles concerned in the expulsive processes may, perhaps, sufficiently explain the tendency both to rare micturition and defecation which sometimes exists. The muscles of speech are often involved, the affection varying in degree from inability correctly to utter one or more letters of the alphabet, up to the entire loss of the articulating power. During the earliest months of life, deglutition is often impaired. The intellectual functions sometimes suffer, from the slightest impairment, which the fond parent unwillingly acknowledges or fails to perceive, up to entire imbecility or idiocy. The functions of organic life are unaffected, except perhaps that of development of caloric, although the depression of temperature may be more dependent on the want of proper exercise. The appetite is good; the frame generally, in average cases, is well nourished, although with less than the average adipose deposit. The child is often described as the healthiest of the family, escaping epidemics, or having these disorders less severely than the brothers and sisters. These subjects often lead a more precarious existence during the first weeks after birth; at first even vegetative life languishes, often because premature birth or difficult labour, by impairing the maternal supply of nutriment, renders more difficult the infant's recovery from the shock the system has received. However, in

¹ See Little, 'On the Influence of Abnormal Parturition on the Mental and Bodily Condition of the Infant,' *Transactions of the Obstetrical Society*, 1862.

the majority of instances, after 'restoration of the vegetative functions, a gradual amelioration of all the functions of animal life is perceptible.

Although at first convulsions are the rule, the *spastic* contractions are not present, or are not observed, until some weeks after birth. The child's limbs are simply weaker; the convulsions and the question of stability alone occupy the thoughts of the attendants. Before the age of three or four months, though sometimes in slight cases not until the ordinary time for locomotion has arrived, the nurse perceives that she is unable properly to separate the thighs or knees for purposes of cleanliness; that the child never thoroughly straightens the knees; that he does not attempt to stand, or is incapable of standing except on the toes, or that the feet are disposed to cross each other. Even children slightly affected rarely 'go alone' before the age of three or four years; many are unable to raise themselves from the ground at that age, and others do not walk even indifferently at puberty without the support of some neighbouring articles of furniture. Locomotive ability seems to advance in proportion as the intellectual powers are developed. The external form of the cranium occasionally exhibits departure from the normal type—such as general smallness of the skull, depression of the frontal or occipital region only; sometimes of one lateral half of the skull, sometimes of one-half of the occiput only.¹ In slight cases the head has been well developed. The *ensemble* of phenomena points to injury more or less extensive of the cranial contents, and especially of the medulla oblongata and spinalis.

In all cases, even with great inertia as to the exercise of volition, common sensibility appears little if at all deficient. On the contrary, a morbid sensibility of the organ of hearing and of the cutaneous envelope appears to exist, evinced by 'startling' at the slightest noises, and extreme sensibility to touch. This morbid sensibility may be due to a condition of spinal cord analogous to that present in narcotized frogs, in individuals under the influence of strychnine, or those affected by tetanus. It may, however, be apparent only, dependent upon the individual, when subjected to common noises, being less competent quietly and promptly to reason upon them, and by thus reassuring the easily disturbed nervous mind, to escape from the exciting influence. In many cases the intellect has been intact. A peculiarity of these children—an uncommon fear of falling—is often observed when they are seated on a couch, less when they are on the floor, and not observed when they are seated in an arm-chair; a circumstance clearly due to conscious inability to balance and recover the position of the body.

Spastic Contractions from Cerebro-spinal Disease in Infancy and Childhood.

We have just described a state of more or less general spastic contraction, which results from disturbance of the cerebro-spinal centres at the moment of birth, either from direct injury to the cranium or neck whilst passing through the maternal parts, or, more probably, from asphyxia consequent upon interruption to the substitution of pulmonary for placental respiration. Sometimes, without premature or difficult labour having preceded, convulsions occur very soon after birth, during the first hours, days, or weeks of independent existence. The author has met with a case of slight disturbance of parturition followed in the child a few days after birth by convulsions, which continued with little intermission night and day for a fortnight. The child recovered and has become robust in mind and body. Convulsions, as is well known, occur more frequently after dentition has made some progress, whilst the infant is undergoing another transition, that of passing through the crisis from nourishment by the mother's breast to feeding, when unfavourable consequences of deprivation of breast-milk are apt to show themselves. The infant may be of previously unexceptionable history, except that the parents may be the subjects of disorders of the nervous system, of nervous temperament, have overtasked brains, have

¹ Morbid anatomy reveals in these cases a corresponding deficiency in size of the affected parts of the cranial contents.

been phthisical, or are intemperate. These convulsions now and then leave the sufferer impaired in mental power, and affected with spastic rigidity, undistinguishable from that which succeeds apnoea and asphyxia neonatorum (see fig. 29). It is scarcely necessary to add to the previous remarks on spasmodic and paralytic contractions that convulsions and other cerebro-spinal morbid states of childhood may be followed by spastic contraction, or paralysis of single muscles or of sets of associated muscles.

Treatment.—The indications for either the operative or mechanical treatment of these different forms of spastic and paralytic contractions, and the mode of conducting the treatment, are the same as those laid down in speaking of congenital club-foot (p. 235), modified by the nature of the cause of contraction. In contradistinction to congenital contractions we may remark that in contractions occurring during teething, the occurrence of structural shortening may generally be prevented by timely-applied manipulations, frictions, mechanical support to paralysed parts, or assistance to the antagonists in the case of spastic affections. It should be remembered as a reason for avoiding unnecessary tenotomy, that the contracted muscle is often the healthier one, and that in the case of a spasmodically affected muscle, tenotomy does not 'cure' the spasm. It is often only temporarily beneficial, and sometimes transfers the preponderance to another set of muscles, merely substituting one evil for another. In severe general spastic contraction, the surgeon has carefully to balance the good and evil of plans of treatment one against the other.

Flat-foot, or spurious Valgus, atonic and rachitic.

This common deformity presents externally many of the characters of congenital valgus, and of the acquired valgus which results from paralysis of the anterior tibial muscle. But the resemblance is only superficial. The person treads unduly on the inner margin of the foot, the toes are turned outwardly, and the arch of the foot is diminished, or, in severe cases, may be obliterated; hence the term flat-foot. True valgus springs from congenital contraction of the peronei muscles; spastic non-congenital valgus from spasm of the peronei; paralytic valgus from partial or total paralysis of the anterior tibial; sometimes combined with paralysis of the posterior tibial, causing contraction of the peronei owing to the want of antagonists; but spurious valgus or flat-foot is due to general want of tone in the fibrous structures of the body—atonic valgus—displayed in the yielding of one of the parts of the frame most exposed to strain, the plantar muscles and ligaments; hence sinking of the arch, eversion of the toes, and secondary contraction of the peronei. In many atonic cases in early life the ankle-joint and foot present a normal appearance when the individual is seated and bears no weight upon them. The only abnormal conditions then present being that of increased laxity and mobility. Other cases have a distinctly rachitic origin, the bones being softened and yielding in consequence of the superincumbent weight. After a time the displacement of the tarsal bones, connected with the sinking of the arch, leads to painful or difficult locomotion and limitation of the movement of the ankle-joint. Finally, the tarsus may become convex inferiorly, concave superiorly, the anterior part of the foot being then drawn up by the conjoint action of the anterior tibial and the extensors of the toes, and the heel held tensely upwards by the muscles of the calf. Even in moderate cases contraction of the peronei is distinctly felt; in severe cases shortening of the remaining muscles above enumerated is also evident. In the worst cases scarcely any mobility of the ankle-joint remains. A slight degree of atonic valgus is common in girls, especially amongst those of fine organisation in the upper and middle classes of society; less frequent in boys, and is frequently curable amongst them by considerably reducing the amount of standing and walking exercise, by substituting horse exercise where practicable, by avoiding too fast walking in the company of adults, by early hours, by avoiding competitive over-study, by generous living, fresh air, tonics, attention to the state of the primæ viæ, embrocations, and manipulations directed to the promotion of inversion of the foot and prevention of the threatened

contraction. In greater relaxation of the parts about the inner ankle, actual confinement to a couch, and carriage exercise for a month or five weeks, or that time spent on the sands or beach at the sea-side, or riding astride a horse without stirrups, will lay the foundation for cure. Boys of the suitable class may be brought up as tailors who work cross-legged. Girls seated on the floor or sofa cross-legged, may with advantage do a part of their needlework or schoolwork in this position, which is eminently conducive to cure eversion of the feet and restoration of the arch. Laced boots, supported at the sides with stiff leather or thin steel busks, are of great assistance in walking. An elastic horse-hair, india-rubber, or felt pad beneath the inner margin of the foot tends to support the arch. Iron and cork, often employed for this purpose, are harsh and inefficient. We must utterly condemn a practice often resorted to in contempt of the pathology of the affection—that of severing the peronei and tendo Achillis in all such cases. The recovery of patients from moderate flat-foot when this operation has been performed, is due mainly to the absolute repose of the limb with which the operation is followed, and to the mechanical measures concurrently employed. But in a few rare cases in private practice, and in those of boys who have stood prematurely behind a counter twelve or fourteen hours daily, and amongst the labouring classes in public hospitals who have suffered from pro-

FIG. 30.—Severe Flat-foot or Spurious Valgus.

maturely carrying heavy weights, the deformity has existed so great a length of time that the contracted muscles have become shortened and rigid, rendering tenotomy, with its promptness and certainty of action, a necessary adjunct to the mechanical treatment.

Flat-foot often exists for several years without attaining even an intermediate grade of severity, when all at once a particularly long walk, a leap, or initiation into a standing occupation, becomes the starting-point of a considerable and rapid aggravation. Sometimes evidence of chronic inflammation of the talcaneo-scapoid ligament, or other plantar structures, or a painfully stretched condition of the plantar nerve, exists. This last symptom is recognised by the exquisite, unbearable, electric-like, painful, tearing sensation described by the patient when he takes a long stride, or stands on the affected leg alone. Sometimes a rheumatic valgoid foot may be recognised as a consequence of protracted rheumatic disturbance of the ankle and plantar structures, analogous to the rheumatic valgoid or in-knee distortion. We should not be induced to operate on flat-foot even on account of its long duration, or of palpable shortening of the tendons before enumerated, since even rigid contraction of muscles, healthy as to their innervation, will yield in a few weeks to judicious frictions, manipulations, disuse of the part (required in this deformity owing to its special exposure to aggravation by walking), and mechanical treatment. As an argument in favour of severing the Achilles and other tendons in slight cases we have heard the question put by a surgeon 'What harm does the section do?'

Now, although the tendo Achillis is very tolerant of the too ready operator's scalpel, it cannot be pretended that an unnecessary operation is a benefit. As, in extremely severe cases, the act of walking, after replacement of the tarsal bones, tends to bear down again the tarsal arch, the aid of mechanical appliances is subsequently needed for several months, or even sometimes for two or three years. Relief is much more readily obtainable in the child than in the adult. The apparatus available in these cases is the same as that used for varus, but with the action of the springs, screws, or lever reversed.

Subcutaneous division of the peroneus longus and brevis is effected in a manner similar to the operation of severing the tendo Achillis. The patient should lie over on the opposite side, an assistant holding the foot inwardly, so as to maintain extra tension of the parts. The tenotome should be introduced in front of the tendons, the section proceeding from within outwards.

Contractions of the Upper Extremity from Spasm and Paralysis.

The principles which should direct the application of tenotomy to spasmodic and paralytic contractions of the upper extremity are those which are applicable to other parts of the body, except in so far as the functions of the individual muscles of the upper extremity, especially those of the wrist and fingers, are more delicate, varied, and complex than, for example, are those of the corresponding parts of the lower extremity. We should be prepared to expect that a surgical proceeding which aims at intercalating a piece of new tendon, with the object of reducing the range of action, and therefore the power of a rebellious spastic muscle, or for the purpose of thereby weakening a healthy muscle so as to favour a partially paralysed antagonist to recover its activity, would be less successful than in the lower extremity, the actions and movements in which are comparatively simple. The acquirement of the power of progression, even if it be incomplete, amply compensates for the sacrifices the patient makes; in bad cases he is satisfied with the possession of a limited flexion and extension of the hip, knee, and ankle, and can be aided by mechanical appliances. But in the case of the wrist and fingers the individual derives little benefit from these simple movements, and he cannot be materially assisted by any complicated mechanism hitherto invented. We have divided the biceps at the bend of the elbow, the rigid well-defined pronator radii teres at its muscular portion, the tendons of the flexor carpi and radialis and ulnaris where most prominent close to the wrist, and have found the resulting benefit proportioned to the attention subsequently bestowed upon manipulations, passive exercises, and painstaking education of the enfeebled non-contracted extensors. Except in cases of many years' duration, in which the retracted muscles were reduced to inextensible fibrous bands, it has seemed that as much ultimate benefit was obtained by manipulations and exercises as by the employment of an operation, and at no greater expenditure of time. This has been the case in long-standing instances of contraction of the pectoral and scapular muscles, forming the border of the axillary region, due to long previous paralysis of the deltoid and probably of the supra-spinatus muscles. The prognosis must be based on the amount of improvement that may be expected in the affected portion of the nervous centres. As an encouragement to treatment, the surgeon should remember that cases occur in which the disorder of the nervous system and nerves has ceased, and that he has to deal only with consequences. This observation applies also to many congenital contractions.

In a case of this nature, osteotomy of bones of the upper extremity was effected with much advantage by Mr. L. S. Little, in 1868.¹

Deformity from Palmar and Finger Contraction (Dupuytren's hand).

This not uncommon contraction in the upper extremity consists in a permanently flexed condition of one or more fingers, with apparently visible and palpable thickening.

¹ See the section on 'Osteotomy' in the essay on SURGICAL DISEASES OF CHILDHOOD, Vol. III.

ing and hypertrophy of the fascia investing the palmar surface of the first phalanx of the affected finger or fingers, and of the neighbouring portion of the palmar fascia. Sometimes the whole of the fingers and thumb are implicated, the palm itself is contracted, and the use of the member as a prehensile, and even as a tactile, organ almost destroyed. The ring and little fingers, the middle finger, index, and thumb, are usually affected in frequency and degree in the order in which we have placed them. The articulations are commonly unaffected, although occasionally that of the first phalanx, with the second phalanx, or this with the third, has exhibited slight arthritic enlargement. On endeavouring to straighten the fingers, the surgeon feels that a general resistance is offered by the tissues of the entire palmar surface of the hand and fingers, and especially by the palmar fascia itself. Any existing tension of the flexor tendons cannot be felt along the fingers, but in the palm, particularly in the upper part, above the edge of the most indurated part of the fascia, one or more prominent and tense tendons may be felt. This deformity is usually attributed to injury, often to a trifling wound, to irritation by the use of a whip in driving, of a walking-stick, or mechanical tool. These mechanical causes, or local irritants, if really operative, can be regarded only as occasional determining or exciting causes. We formerly believed the essential or primary cause to be a constitutional one, allied to the gouty or rheumatic diathesis. We may not venture, however, to assert that the constitutional cause is identical with that of gout or rheumatism, as the persons affected have appeared singularly free from other manifestations of those affections. The affection of the palmar fascia, unlike gout or rheumatism, is painless. An occasional patient affected with considerably contracted palmar fascia in both hands may present similar affection of the corresponding fascia of the soles; a sufficient proof that the complaint is essentially independent of the mechanical causes assigned for it,—unless, indeed, we assume that the act of walking by stretching the sole can act upon the plantar fascia and muscles after the manner of a mechanical irritant. The symmetrical character of the affection, the precise resemblance of one case with another, the frequent occurrence of the same deformity in father and son for several generations (four), as well as the above facts, confirm the opinion of its constitutional origin. We have never witnessed this complaint in the female. My patients affected with it have not been 'total abstainers.'

Formerly we regarded it as a painless chronic induration of the fascia, leading to compulsory, gradually increasing disuse of the fingers and hand—that through this disuse the flexor muscles and tendons, being probably free from the original affection, asserted their preponderance over the equally idle extensors, and became gradually affected with secondary shortening.

The normal hand, placed as near as may be into the shape of one of these very contracted hands, so nearly resembles it, except as regards the absence of distinct contraction of tissues, that it is difficult not to believe that the skin has as much to do with the prominent ridges and furrows as the fascia, and that they are both thrown into folds by muscular action; in fact, that nerve muscle and tendon are the primary agents in the contraction, and not the fascia, as Dupuytren and subsequent writers (ourselves included) maintained. Often a prominent flexor tendon is predominant in the palm; we have seen the palmaris longus muscle and tendon in the forearm tensely contracted (see a case of this kind in Dupuytren¹). When the patient is requested to

FIG. 31.—Contracture of Palm and Fingers. The habitual state of the hand was one of greater contraction; the drawing represents the appearance when the patient endeavoured by muscular action to extend the fingers.

¹ *Sydenham Soc. Works*, vol. 1854. In the case in question, Dupuytren, it would appear, impressed with the idea of the dependence of the complaint upon disease of the

act upon the muscles of the forearm, the above tendons are rendered more tense and the distortion is increased. Doubtless the office of the palmaris longus is to render the palmar fascia tense. On full consideration of the arguments we could adduce for or against the nervo-muscular theory of the origin of this distortion, we arrive at the conclusion that this is the true cause and not *disease* of the fascia.¹

Treatment.—Even in tolerably advanced cases, frictions, manipulations twice or oftener daily, the application of a screw-adjustment splint, or straight splints of wood, tin, or gutta-percha, will, if suitably and perseveringly used, reduce the contraction and deformity. But at the advanced age at which many patients present themselves for relief, the employment of mechanical apparatus encounters many difficulties. In rigid unyielding cases of long duration, subcutaneous section is remarkably efficacious. We cannot by its means alter the constitutional state, or instantly remove the induration of the fascia; but we are enabled to remove the contracted bands by subcutaneous section, and, so far as the contracted muscles are concerned, to take the case entirely out of the influence of the patient's will, and obtain a starting-point for further benefit by mechanical treatment. A puncture half a line in width suffices for the passage of a firm tenotome beneath the fascial band or the tendon in the palm. The division is effected from below upwards. No fumbling or unnecessary handling of the part after the operation, by which means air or blood might be disseminated amongst the palmar tissues, is permissible. The operation, like most subcutaneous operations, is bloodless. We have invariably seen the puncture heal within forty-eight hours. Considerable yielding or entire straightening of the contracted finger, the tendon of which has been severed, is at once perceived. We have rarely needed to sever more than two or three bands of fascia or tendons. Sometimes small contracted fascial or tendinous slips in the palm opposite the lower ends of the metacarpals, or passing between the fingers, when divided, afford instantaneous relief. It is necessary to mention that when a known flexor tendon has been severed in the palm, so that the finger could be bent once entirely straightened, no immediate extension of the finger should be resorted to. The object should be to obtain no greater lengthening of a tendon than is needful. By supporting the wrist and fingers on a moderately bent flexible metal splint, the divided tendinous ends are brought near enough for agglutination. When the patient is seen to be able to move the finger, the part can be gradually extended without pain. If only fascial bands have been severed, extension should be made directly the puncture has cicatrised. It has been recommended in these cases to make, if required, as many as ten to fifteen subcutaneous sections of fascial bands, and under anaesthesia to forcibly straighten and bind the parts immediately upon straight splints. We have never needed to make these multiple sections nor to risk delay in healing by immediate stretching of the punctured cutis. The cutis is so firmly attached to the fascia that the one cannot be stretched without the other. When a single most retracted tense tendon in the upper part of the palm is severed, the whole complaint often yields at once. Manipulations and mechanical treatment complete the cure. We have frequently thus effected entire restoration of the hand and fingers. It is remarkable that the indurated structure quickly softens, and the hard ridges and corresponding furrows disappear, under this treatment. The rapid disappearance, within two or three weeks or a month, of the slight coexisting wrist contraction and very hollowed palm, as well as of the hard ridge and furrows which had existed several years in the palm, and at the root of the phalanges, has for a long time seemed to us an indication that they were due to a cause contracting those parts from a distance, such as one or more of the muscles of the forearm, including the palmaris longus, would be. It may be that the afflux of blood to the part excited and maintained by the frequent manipulations, frictions, and bandages, alters the nutrition of the part, and removes the previous morbid deposit, if any. It is also probable that caution as to diet and wine, whilst under the observation of the surgeon, assists this process of palmar fascia, rejected the case because it pointed to dependence upon contraction of the palmaris longus.

¹ See Paper by the author in *Hunterian Soc. Trans.*, 1870.

recovery. The causes being constitutional, and the attention of the patient being liable to slacken after a lengthened recovered use of the member, the complaint occasionally returns, as do many other diseases.

Wry-Neck. Neck injury at birth.

Torticollis, or wry-neck, is not an uncommon distortion of the head and neck, originating, like club-foot, from a variety of influences; some acting through the muscles—congenital, spasmodic, paralytic; others acting through the ligaments and bones—rheumatic and strumous. Occasionally the point of departure of a case is strumous affection of the lymphatic glands, and sometimes loss of textures from sloughing after burns or a gunshot wound.

Congenital wry-neck.—This is the most common form of wry-neck. It is perceived a few months or more after birth, and, when suffered to proceed unchecked, gradually increases during childhood, adolescence, and adult life, until it attains the proportions of a formidable deformity. Many cases of wry-neck, reputed to be congenital, have appeared to originate from accidents at birth, in consequence of breech presentation, turning, &c. Infants have been brought to us a few weeks old with the neck observed to be unusually weak or loose from injury at birth. The muscles

FIG. 32.—Wry-neck from active Contraction of Sterno-cleido-Mastoideus.

appeared as if paralysed, for the connection of the head with the shoulders was looser than usual at the corresponding period. They recovered with a few general directions as to position and support by the hand when dressing or turning the child over. We will describe a young adult case of wry-neck, in which the right sterno-cleido-mastoideus is the head and front of the offending, for it is probable that other muscles are always either primarily or secondarily involved. The entire head leans to the right side and slightly forwards, the right side of the neck is somewhat hollowed, whilst the left side is unnaturally convex, and the patient not unfrequently complains of pain in this situation. The chin is drawn to one side and approaches the left shoulder; the right ear is approximated to the sternal extremity of the clavicle. The sterno-cleido-mastoideus of the affected side may, as in fig. 32, be well developed. Sometimes it has lost its symmetry, being reduced to a comparatively narrow, hard, tight cord, three inches in length, the muscle of the opposite side measuring five and a half inches. This prominent cord may be double below, representing the double origin of the muscle. In the adult a marked upward bend of the clavicle is often seen where the clavicular portion of the contracted muscle arises, induced by the constant abnormal traction to which the bone has been subjected, and the inferior portion of the muscle itself appears of cartilaginous hardness, and is lost in a large bony process on the protuberant clavicle. If we examine the neck and shoulders posteriorly, we observe that the cervical vertebrae have yielded to the dragging of the

contracted muscle; the column presenting a convexity on the left side, which is compensated for by a curvature in the opposite direction lower down. The right side of the head, neck, and right shoulder are considerably smaller than the parts on the opposite side; the right shoulder and scapula being unduly raised. A singular effect upon the face results from this difference in size, combined with the impediment to the function, which the abnormal position of the head involves. In the adult case from which we describe, so great is the difference in size between the two sides of the face, that on the right side the external canthus of the eye is distant from the external angle of the mouth three inches, whilst on the left the distance amounts to three and a half inches. The inclination of the head to the right causes the right eye to be habitually situated on a still lower plane than would be the case if atrophy of the affected side were alone operative. The atrophy and the slight bending forwards of the head interfere with the direction and use of the right eye, and causes a peculiar expression of archness or sense of difficulty and suffering. After successful treatment the disproportion of parts, even in aged individuals, is much lessened.

The principal muscles of the neck are sometimes involved, the trapezius and scapuli, as well as the sterno-mastoid. In this and other respects congenital wry-neck offers much analogy to congenital club-foot. The principal contraction affects in both cases muscles which pass over more than one articulation, the sterno-cleido-mastoid in one case, the gastrocnemius in the other; hence in the neck the mischief of morbid contraction may effect a higher degree of deformity than if the contracted muscle influenced one articulation only; in the leg the contracted gastrocnemius does not always limit its evil influence to the foot, but may contract and distort the knee. In both wry-neck and club-foot other muscles participate in the deformity; but the range of influence of these being less, or being counteracted by antagonistic powers, their contraction is not so apparent. It is an interesting question of physiological pathology whether there is anything special in the anatomy and function of the sterno-mastoid and gastrocnemius, that they should obtain the distinction of entering into so large a proportion of cases of congenital and acquired deformity. The gastrocnemius, by its great development, its greater nervous supply, and its relation to the upright stature and locomotion of man, is certainly entitled to a peculiar and elevated rank in myology; so, when we reflect upon the size of the sterno-cleido-mastoid, its relation to the large vessels of the head and neck, its deriving its nerve-power mainly from a special nerve (spinal accessory), and remember the influence of this muscle upon the act of respiration, we cannot deny it a pre-eminent function amongst its neighbouring muscles.

We have elsewhere shown¹ that not unfrequently wry-neck appears to result from straining or injury to the neck during difficult labour, from traction of the head by instruments. It is superfluous, after what we have said of the causes of congenital club-foot (p. 231), to refute in detail the theory which would attribute every case of wry-neck, like club-foot, to accidental uterine or pelvic pressure during birth. The greater number of cases of congenital wry-neck clearly originate from causes acting through the nervous system.

Treatment.—As with slight congenital club-foot, so slight cases of congenital wry-neck, if detected during the earliest months of life, are removable by frictions, manipulations, and subsequent education; but the majority of cases which we have treated, varying in age from four to forty-five years, have exhibited so much contraction and proportional secondary deformity, that we have rarely delayed operation when the patient had reached four or five years. It has always seemed advisable to gain at once, by means of this operation, a large measure of relief; thus affording an encouraging starting-point for the after-labours of the attendant in overcoming the shortening of the integuments, platysma, fascia, associated muscles, and ligaments on the hollow side of the neck, and, in this way, gradually acting upon the altered relation of the articular facets of the inclined vertebra, or counteracting the tendency to such alteration.

¹ *Trans. Obstet. Soc.* 1862.

Division of the sterno-cleido-mastoideus is performed subcutaneously, upon the principles laid down by Stromeyer in division of the tendo Achillis, viz. effecting the division by the smallest possible wound in the integuments and the narrowest tract through the subcutaneous tissues, and avoiding any external bleeding or extravasation of blood into the areolar tissue, or admission of air into it. Neglect of these precautions, in this particular situation, would be calculated to excite suppuration and prevent immediate healing of the puncture, and delay untowardly the employment of the necessary after-treatment, until, perhaps, the severed tendon might be too closely reunited. The spot chosen for the operation may be that at which the tendon springs rigidly across the important subjacent organs, and where consequently most space is afforded for the introduction of an ordinary slightly convex-edged tenotome beneath the tendon without risk to those organs. In wry-neck this spot will be found from a half to one inch above the clavicle. It is also more easy to sever the muscle entirely by keeping at this distance from the bone. In some cases we have found the sterno portion only developed and rigidly contracted; a few weak fibres attached to the clavicle having, before the knife reached them, yielded to the tension maintained by the assistant. In cases in which the clavicular origin of the muscle is broad, it is safer to divide the sternal and clavicular portions each by a separate puncture, rather than pass the knife by one puncture made in front of the neck as far back as may be necessary to reach the whole of the clavicular portion. This precaution is justified by the anterior and posterior edges of the muscle not being on a plane surface; for, although the fasciæ of the lower part of the neck may usually bind down sufficiently the vessels and nerves, and so keep them out of danger, it is well to remember the liability of meeting with abnormal distribution. The complete division is accompanied by a very sensible crack, and the head at once assumes a much improved condition. We have measured immediately after operation, and have found the difference in length between the affected and sound muscle reduced more than one-half, but we have avoided before cicatrization of the puncture fixing the head in the most improved position. The puncture should at once be covered with a compress of lint, and a common bandage be applied. We have found no harm result in the case of the sterno cleido-mastoid in allowing the ends to separate as far as they were inclined to yield. In a few cases of very young children we have of late preferred dividing the muscle in the old situation, in the middle of the neck. In this situation we raise up the entire muscle between the left forefinger and thumb, pass the sharp pointed convex-edged tenotome through the integuments behind the muscle, keeping the flat surface of the instrument towards the muscle until the point touches the forefinger. On removing the thumb, whilst keeping the forefinger at its post, the convex edge of the tenotome is turned upwards, towards the muscle, which cuts itself completely through before, or whilst the surgeon gradually withdraws the knife; no to-and-fro movement of it being requisite. The surgeon's left forefinger should follow the retreating knife and cover the place of entry, permitting no oozing out of blood or entry of air, until he has covered the part with a small dossil of lint and secured it with a light turn or two of a roller bandage. Although we have operated on a large number of cases close to the clavicle, owing to the former belief that it was preferable to sever tendinous rather than muscular tissue, the present more promptly and neatly done section, not *à deux temps*, with a small knife in the middle of the neck, leaving no appreciable scar, offers the greater advantages.

In young and flexible subjects, we have found adhesive plaster and a common roller-bandage an amply sufficient mechanical contrivance to aid in rectification of the head. Apply a long strip of adhesive plaster around the forehead and occiput, its maintenance in position being better secured by a bandage passed over the vertex and beneath the chin, the two being pinned together where the one passes over the other, above the ears. Next attach around the waist a broader band of adhesive plaster, not so tight as to interfere with the movements of the ribs; over this a turn or two of calico roller-bandage; the two should be fastened together by a stitch here and there. The surgeon has now two circular bandages, the one around the

forehead, the other around the waist, which are not likely to slip if properly applied. He then should sew a strip of tape to the head bandage directly above the ear of the unaffected side, and carry it diagonally across the trunk to the opposite side of the waist bandage, and there pin it. By this means the left mastoid process (we are speaking of wry-neck caused by contraction of the right sterno-mastoid) will be drawn towards the right sterno-clavicular articulation, the original wry-neck be removed, and the chin brought to the median line, or in young and flexible subjects even across it, towards the affected side, constituting a temporary wry-neck in the opposite direction. The circular or ovoid form of the cranium renders it difficult to act upon it for any length of time by any other apparatus hitherto invented. The apparatus will shift its direction, or rather the head will partially disengage itself. Hence even a greater necessity for manipulations exists in congenital wry-neck than in other deformities. No apparatus effects so beneficial and lasting an impression upon the distortion as that which can be effected by the hands of the surgeon or attendant. There is a great additional advantage in the patient being freed from the burden and annoyance of the complicated apparatus often recommended. Whilst sitting in front of the patient, the attendant should be taught by the surgeon to apply firmly his flat hands to the sides of the head, and direct the chin, vertex, or occiput in the required directions. The patient should be placed on a lower seat. Such manipulations need to be done with due caution and technical skill. It is not necessary to cause pain in order to produce much good. They should be employed three or more times a day. The plaster and roller-bandage which we have described is most convenient in reference to these manipulations. It may be unpinned in a moment, and as quickly readjusted. We have cured many cases by the means here enumerated, in periods varying from one to three months, and have only once had occasion to repeat the operation, because in that case we had left a portion of the clavicular origin of the muscle unsevered. It is not always easy when dividing separately the clavicular portion to determine whether a few fibres of undivided tense structures be muscle or fascia. It was this case which, at the second operation, induced us to revert to the old operation in the middle of the neck. Manipulations as a precaution against relapse may be longer resorted to; but the patient's voluntary efforts are more employed, for obvious reasons, and are more successful, than in some other congenital deformities.

When the patient is old enough the surgeon will find the greatest assistance in encouraging the patient to sit before a looking-glass, to hold the head straight, and practise all the natural movements with accuracy. It is lawful to excite the proper pride of the individual by such gymnastics. An apparatus similar to that generally resorted to for rectification of the position of the head in deformity from vertebral disease, may be employed in cases of *adult* congenital wry-neck during some portion of every twenty-four hours. It readily effects re-position of the lateral or forward inclination of the head, but is powerless to affect the abnormal rotation of the head round the horizontal axis.

Wry-neck from contraction of clavicular position only of the sterno-cleido-mastoid.

—In a few cases of congenital wry neck we have found the sternal portion or the clavicular portion alone contracted; in these instances we have severed the single contracted origin, the cases having done well.

Acquired or non-congenital spasmodic wry-neck.—We have seen many cases of active, violent spasm of the sterno-mastoid in both sexes, oftenest in unmarried females of middle and advanced age, causing severe wry-neck (see fig. 32). The spasm is commonly jerking, irregular, convulsive, never ceasing entirely whilst the patient is awake. The disorder has usually commenced a few years before or after the age of thirty in subjects not always obviously hysterical, persons of excellent intellectual and social characters, whose families have seemed prone to other cerebro-spinal affections. We have watched several of these cases for many years. The spasm and deformity have in many cases gradually increased, often rendering the patient's existence distressing, through incessant motion of the head, disturbance of sleep, and pain in the neck, apparently due to strain of ligaments and nerve-dis-

turbance, and sometimes accompanied with pain referred to the upper part of the spinal cord itself, as in some cases of 'spinal irritation.' Now and then the spasm is so considerable that the ear of the affected side is drawn down by a series of jerks so as almost to touch the clavicle. The patient's voluntary efforts to arrest the pulling down of the head appear to increase the disorder. Sometimes the co-existent affection of the trapezius draws the head at the same time backwards, and prevents the chin approaching the sternum. In inveterate cases, such as have existed many years, we have employed mineral and vegetable tonics, galvanism, and electricity, with only temporary benefit. However, as might be expected, generous diet, hygiene, and freedom from mental disturbance, alleviate the symptoms. Complete relief is afforded by subcutaneous section of the affected sterno-mastoid; but even this measure is only useful for a time; for after two or three months, or as soon as reunion of the severed part is complete, the spasmodic shortening and jerking return. Stromeyer had a patient who submitted to two repetitions of tenotomy for the sake of the temporary relief afforded by the operation. The author once operated on an elderly female who had suffered from spasmodic wry-neck upwards of twenty-five years. She had been unable for many years to sleep in the recumbent position, but dozed in a high-backed nurse's chair, provided with side-supports for the head. For a few nights after the operation she slept soundly in bed. The malady, however, returned, and two or three years afterwards she sank exhausted, want of sleep appearing to be a principal cause of the fatal result. The operation on the sterno-mastoid is insufficient to affect the remaining muscles, which are sometimes involved.

In two recent cases of this affection, such for example as have existed less than two years, we relieved the patients in a few months, using bromide of potassium with quinine and other tonics. In others the use of the perchloride of mercury has had the most satisfactory effect. In every case which the author has cured, using internal remedies, the value of attention to the *primæ viæ* has been apparent. For this purpose, half a grain of the ext. aloes barbad. every night has been used. The utility of hydr. perchlorid. and of argent. nitr., in these and analogous cases, may be due as much to their stimulant action upon the hepatic and alimentary mucous surfaces, as to any specific action upon the nerve-tissue serving the implicated muscles. Relapse is not uncommon after every mode of treatment.

An interesting instance of almost perfect cure of an inveterate case in which mere section of the sterno-cleido-mastoid had proved only temporarily beneficial, is fully recorded by Mr. Campbell De Morgan in the *British and Foreign Medico-Chirurgical Review*, July 1866. The successful operation consisted in division of the external branch of the spinal accessory and the removal of a piece of the nerve, about a quarter of an inch in length. The patient was seen some two years afterwards with only faint traces of the disorder.

In obviously hysterical wry-neck in the young female, even of only a few months' standing, and which might have resulted from emotional influences—a condition which we are unwilling to term mimetic, for we could not learn that she had ever seen a similar case—a judicious amount of sympathy, for the pain which really exists on the side opposite to the contraction, combined with the assurance of possible cure, by her own exertions in front of the looking-glass, and a little good-natured banter on the improvement in appearance, on holding the head straight, even for a moment, many times a day, result in the acquirement of increased strength by the will and the normal muscles. These gymnastic efforts undoubtedly greatly help, if they do not wholly effect recovery, when supported by the infused belief in ultimate cure. We may here state that we have never met with a decidedly hysterical case of foot, limb, spine, or neck deformity in the young which did not finally recover. They differ widely in this respect from the older spasmodic cases, occurring about the climacteric period.

Paralytic wry-neck is rare; we have not seen more than three cases. The head is drawn to one side by the healthy muscle, which is deprived of its antagonist. In paralytic wry-neck, when the stage for ordinary treatment of the partial paralysis has passed, we can do no more than support the head by the padded leather or steel

spring cravat. Except when the unparalysed sterno-mastoid is structurally degenerated or very rigidly contracted, and is insusceptible of elongation by manipulations or mechanical treatment, it would be as irrational to employ tenotomy as it is in a case of contracted gastrocnemius, which has simply lost its antagonist, and which can be relieved by a suitable mechanical support without operation.

Wry-neck from disease of the cervical vertebræ is caused by strumous, and sometimes by rheumatico-strumous disease of one or more cervical vertebræ, from which the head inclines to the affected side. The chin is directed to one side. In bulging of the opposite side of the neck, and in general appearance, these cases much resemble congenital wry-neck, but are distinguished from it by their history, the pain on motion, the aspect of strumous or constitutional disorder, sometimes by hectic, by the instinctive aversion of the patient to the surgeon's handling of the head, and concomitant glandular or other forms of strumous disorder in one case, or rheumatic affection in the other. The pathological changes common to disease of the vertebræ in each region, and its peculiar dangers when situated in the neck, are described in a subsequent essay. Great caution is necessary in handling these cases, lest the disintegrating bones give way suddenly to the pressure, or the reparative process which may be going on be interrupted. Much benefit to the disease itself, and gradual improvement in the position of the head and neck, and even rectification, may be effected by a well-adjusted apparatus, as well as by the recognised medicinal, dietetic, and hygienic treatment of the constitutional malady. We have twice witnessed death, as sudden as in apoplexy, in cases in which suitable support of the head had been neglected, and the patients had persisted in maintaining the erect position, having walked about supporting their heads with the hands. These cases are analogous to death from sudden and quickly fatal paraplegia in cases of advanced disease of dorso-lumbar vertebra in which absolute recumbency had been neglected. An efficient apparatus consists of a padded metal plate, secured by straps beneath the axilla and around the chest upon the shoulder of the side to which the head inclines. From this shoulder-pad an iron upright piece extends upwards, by the side of the neck, to the parietal region. The lower end of this upright is attached to, and moves upon, the shoulder-plate by means of an endless ratchet-screw; the upper end is connected with a pad intended to be adjusted and pressed against the parietal region. In adults and very severe cases, this apparatus may be attached to a common spinal support for the chest and pelvis, for the sake of greater fixity and more powerful leverage. Sometimes an iron stem is required to extend upwards to one or both sides of the head, with connecting straps to be applied beneath the chin and occiput, so as to receive the weight of the head. We do not commonly find it necessary to employ the cumbersome and unsightly machines, consisting of an iron scaffold and gibbet for suspension of the head, to which surgeons resorted as lately as the commencement of the present century.

Knock-knee, In-knee (Genu valgum).

* Genu valgum is an alteration in the form and relation of parts of the knee joint, which is apt to accompany the majority of disorders to which the joint is liable. There are therefore almost as many clinical varieties as there are knee affections, and the distortion may also arise in the overlaid, and overworked, but healthy knee.

In-knee has commonly been treated of under two heads: (1) *the Statical*, caused principally by the action of gravity; (2) *the Rachitic*, in which softening of the bones and relaxation of the ligaments and muscles have been the primary causes. It is, however, obvious that, if the subject of such relaxation and softening attempts to stand erect or walk about, statical influences will come into play as much as in those cases called statical.

Genu valgum may exist in slight degree at birth, may originate in the fast-growing year-old infant, from want of breast milk, or from improper and too-watery diet, without external signs of rachitis; or it may depend upon unequivocal rachitis, upon infantile paralysis, upon ordinary spasm from cerebro-spinal disease, or that

which follows asphyxia neonatorum. The non-rachitic form arises less frequently in the later years of childhood during convalescence from any of the acute disorders of that period, when the patient is too soon allowed to stand and walk. On the approach of puberty in both sexes during another period of fast growing, say from the twelfth to sixteenth year or later, a liability to the non-rachitic distortion occurs, increased in the labouring classes by overlading and over-exercise of the limb, and the respiration of the deleterious atmosphere of the workshop. At any period, injuries as well as white swelling (strumous synovitis and ostitis) are apt to present, besides subluxation and contraction in the flexed position, a marked inward inclination of the knee, with eversion of the leg. This is also true of rheumatic knees, especially in chronic cases.

We have seen considerable in-knee in tall, robust, over-stout and overgrown adolescents and adults, height and weight having equally contributed to it.

This greater liability to genu valgum rather than to the opposite deformity (genu extorsum) is determined by the natural form, relations and functions of the parts. In a sound knee, the active and passive structures, the moving and resisting forces are so balanced, that while the normal relations are preserved, a large capability of use beyond the average limits exists.

FIG. 33.—Genu Valgum from Rachitis; one foot being inclined to Valgus, the other to Varus.

In-knee has been directly attributed to the normal greater size of the internal condyle, to the normally adducted position of the femur, to the asserted naturally less developed condition of the outer articular surface of the tibia, to the known greater normal range of abduction of the leg over adduction, in some positions of the knee, and lastly to abnormal contraction of the biceps muscle.

These circumstances favour the production of in-knee only when morbid alteration of the parts concerned in the joint, intrinsic and extrinsic, from overwork, or any of the forms of knee affection, exists. When, therefore, the surgeon treats the early stages of a disease apt to be complicated by knock-knee, he can, by suitable treatment, prevent its occurrence.

Symptoms.—Inclination of the knee inwards is easily recognisable in all its stages, from the slightest departure from the normal, in which the inner ankles, when the patient lies supine, are separated only two or three inches, or one knee when erect slightly overlaps the other, to the more considerable deformity, in which, as fig. 33 shows, the feet are separated ten or fifteen inches. When the surgeon places one hand against the inner aspect of the knee, and the other against the outer malleolus

in a young child, he will in most cases, by gentle handling, straighten the limb, and will note that a considerable undue 'play' in the horizontal direction exists. When thus straightened, he can almost insert his forefinger into the gap formed between the external condyle and the upper part of the tibia (see fig. 34). The extent of this gap is a measure of the extent to which the weight of the body acting on the relaxed and softened structures has altered their relation to one another at this part, causing knock-knee. This gap is much more obvious and greater in atonic or non-rachitic 'statical' cases than in rachitic cases, because the joint is in the latter less lax; it is even sometimes imperceptible, because the softening of the bones in rickets may allow the articular surfaces to mould themselves to one another, and even in children three years old the knee-joints may be comparatively firm and unyielding.

In older neglected cases of in-knee, with little or no traces of rickets (see fig. 35), the ankles may be separated more than twenty-four inches, walking, however awkwardly, being almost impossible. A remarkable feature of the distortion is that it disappears when the knees are flexed, the joint structures being then relaxed. Hyper-extension of the joint accompanies knock-knee, especially the undoubtedly non-rachitic form. It has never before been pointed out that in young rachitic

FIG. 34.—Schematic representation of Genu Valgum.

FIG. 35.—Extreme Adolescent Idiopathic or Atonic Knock-knee.

FIG. 36.—Considerable rachitic Genu Valgum, due in reality mainly to great curvatures of femur and tibiae; from A. Meyer.

a, the femur; b, the tibia; c, the projecting knee-joint; d, dotted lines representing the tibia placed in its natural position; e, gap on the outside of the joint.

knock-kneed children, the reverse of hyper-extension—viz. deficient extensibility—exists, with which the surgeon may have to deal, as well as with curvature of the shafts of the bones and inward inclination of the knee in the same limb.

Sometimes the so-called genu valgum in rachitic subjects is due, as in fig. 36, more to curvature of the shafts of the bones than to disturbed relation of the parts of the joint itself.

In fact, we find that many of the cases regarded as rickety genu valgum, successfully treated by osteotomy, have not been rachitic according to our definition of the term (inward yielding of the knee-joint), but indiscriminately either statical, non-rachitic ones, rachitic ones, or cases of curvature of the shaft causing apparent knock-knee.

When the bones, from a case of severe genu valgum, are disarticulated, and placed as in the normal limb when the body is erect, the gap just alluded to is seen as a triangular space between the external articulating surfaces, the base of which may measure from $\frac{1}{4}$ to 1 inch, according to the severity of the case.

This gap constitutes the grave anatomical fact which the surgeon in the treatment of the majority of cases has to keep in view.

Treatment of knock knee.—We have heard it maintained that, as a rule, children recover spontaneously from this affection. In a small proportion of cases, spontaneous recovery of good power of walking takes place; but an examination of such instances has shown us evident traces of the affection in some persistent projection of the internal condyles, with inability to take long walks on several successive days, without weakness and pain on the inside of the knee. Slight cases will recover under improved dietetic and hygienic influences, with the aid of suitable manipulations, and the discontinuance of prematurely urging the child to walk. Sometimes we can, in addition, advantageously recommend the recumbent posture during certain short periods of the day, and combine with this repose the placing a soft pad between the condyles, the limbs being extended, and the ankles being gently drawn towards each other by means of a soft bandage, strap, or other ligature, or by the hands of the surgeon or of the 'rubber' who has been taught by him (see figs. 37 and 38).

Long-continued experience has shown us that two things are indispensable—viz. to

FIG. 37 represents a moderate degree of Knock-knee in the act of manual reduction. If the surgeon prefer, he may teach the rubber to accomplish the same upon each knee singly, by pressing the internal condyle with one hand, and the outer malleolus with the other.

FIG. 38 represents the same Knees as fig. 37 when straightened with the hands. During these manipulations it is absolutely necessary that the patellæ should present upwards, towards the ceiling, not sideways.

keep the knee extended during active treatment by an unyielding padded splint of any material along the back of the joint to prevent its bending, and to apply a similar contrivance along the outside of the joint to maintain *adduction* of the leg.

The *side* splint should be thickly padded along one-fourth of its length only at both extremities, leaving the middle portion unpadded so as to present a hollow into which the joint may be drawn by a roller bandage or straps and buckles (see fig. 39). Should the case be more severe than in the above figure, or any difficulty be experienced in accommodating a flat straight back splint to an inwardly inclined knee, a light wood or metal splint (fig. 40) may be employed; being articulated horizontally, it accommodates itself to the angle of the distorted knee, but effectually prevents bending, and does not interfere with the action of the side splint. We prefer these splints to the metal troughs furnished with straps and buckles which we introduced a generation ago.

Children of the well-to-do classes with slight knock-knee may, with or without the use of splints, at night, and some two or three hours in the day-time, spend a part

of their day at book or needlework, sitting on the ground with knees crossed, and their work in front of them. Every occupation that frees the outer side of the knee-joint from pressure is desirable. Pony or donkey exercise astride without stirrups when available, very useful.

FIG. 39 represents the Side Splint along the outside of the knee before the roller bandage is applied. The plain straight back splint, which should be applied before the side splint, is not represented here.

FIG. 40.—Dr. Little's improved Articulated Back Knee-splint for instrumental treatment of In-knee.

FIG. 41.—Diagrammatic representation of Walking and Night Instrument for rectification of severe Adolescent Knock-knee. It consists of an upright stem, with free movement joints at hip and ankle, attached below to an ordinary foot-piece, and transferable to an ordinary day boot, to which it may be secured by a spring below the heel.

FIG. 42—Right In-knee, with hyper-extension and out-knee on the left side, with general outward curvature of the limb. From Macewen, 'On Osteotomy.'

a a, on the upright stem are pads on the fulcra to protect the skin over the trochanter and the external malleolus from pressure; *a*, on the inside of the knee, is to indicate a pad to protect this part from pressure. Leading from this pad to the upright stem is a metal back-piece, consisting of two parts, the left-hand half being the female screw, and the right half a male screw. By turning round the piece of metal *a* to which the male screw is attached, this is made to enter the female screw, so that gradually the piece *a*, opposite the inside of the knee, is approximated to the upright stem, and the inverted knee-joint gradually directed towards the perpendicular. To avoid encumbering the drawing several adjuvant essential contrivances have been omitted. These are a thigh strap, which should be attached to the upright stem, opposite the middle of the thigh, to draw the thigh towards the perpendicular; a similar should be opposite the middle of the leg. Besides these a stout buckskin strap should pass from the upright at *b b*, successively over the front, the inside, and around the back of the knee, and be buckled on the upright at *d d*, so as to draw the knee outwardly; and another buckskin strap pass from the buckles *c c* to the buckles at *d d*, so as to keep the knee completely extended. It is desirable that once a day the knee in the still growing individual be bent, so as to avoid stiffening of the joint in the extended position. It is well to order the apparatus to have a ring-catch knee movement. If the knee of the worst class, whether or no section of *biceps femoris* has been done, be, as it should be, straightened within eight or ten weeks, the patient may be allowed, by means of the ring catch, to walk with free movement of the joint a part of, or after a time, the whole day.

Infants even who are unable to walk evince no pain or inconvenience from treatment. If the utmost gentleness be used, nature will do her work in filling up the gap between the external condyle and opposite part of the tibia; and certainly, on removal from the joint of the undue direction and pressure of the weight of the body, the ligaments and muscles will adapt themselves to the new order of things. With improved nutrition infantile cases are remediable within two or three months, not needing afterwards irons or retentive apparatus of any kind. Children of two to four years and upwards able to walk, if the case be more severe, may wear the apparatus (wooden splints or common leg irons, with or without 'ring catch' arrangement, as the necessities and severity of the case may indicate) day and night, and walk about in the day-time with reasonable rest, the apparatus being removed morning and evening for cleanliness sake, and to enable the nurse to bend methodically the knee-joint once or twice, *i.e.* preventing inversion. Patients may follow their nursery school or business vocation. As soon as it is found that the knees evince no decided tendency to return to the valgus form, directly the apparatus is removed, a gradually extended permission to habitually use the limb in full mobility may be given.

A tall adolescent may be successfully treated throughout by the splints at night, and a long straight iron outside from pelvis to the ground, not jointed at the knee, during day-time. It is rarely necessary in any but the severest neglected or unrelieved cases, even in the adolescent up to the age of 16 or 17, to confine the patient to couch or bed, to resort to tenotomy, division of ligaments, or to forcible straightening under anaesthesia.

If force be absolutely necessary, we prefer supra-condylar osteotomy, especially as carried out by Macewen, remembering that the division of bones is rarely required for the relief of the essential nature of the knock-knee joint distortion, but only for the otherwise insuperable rachitic coexisting curvature of thigh and leg bones; in fact, for relief of severe rickety curvature in advanced adolescence and adult age, to which it should, in our opinion, be restricted. (See the section on 'Osteotomy' in the essay on SURGICAL DISEASES OF CHILDHOOD, VOL. III.)

Occasionally the knee-joint yields outwardly instead of inwardly, constituting a deformity exactly the opposite to knock-knee (see fig. 42). We have named this affection, *Genu extorsum curvatum*. The treatment of it should be conducted upon the same principles as that of knock-knee, but be applied in the opposite direction. Sometimes we have to treat in one limb genu valgum and in the opposite limb genu extorsum curvatum, the latter being the more obstinate under mechanical treatment, and therefore needing earlier recourse to osteotomy of thigh and leg bones.

Anchyllosis of the Knee and other Articulations.

The successful labours of orthopædic practitioners have contributed to improve the knowledge of the real condition of joints after the cessation of various forms and degrees of injury, inflammation and degeneration. The erroneous notion, that long-continued repose of a joint alone sufficed to induce such alterations in its articular surfaces as to lead to bony union, and the remarkable rigidity and immobility which result from the agglutinated or contracted extra-articular structures—*fasciæ*, muscles, and ligaments—especially when dense, fibrous, deeply-extending cicatrices co-exist, favoured the supposition of the common prevalence of true bony, irremediable anchyllosis. We know that absolute bony union of articular surfaces is a comparative rarity, even in pathological cabinets.

For practical purposes we may divide the conditions in which joints contracted from disease are presented to the surgeon, with a view to the restoration of form and motion and restoration of symmetry, into three classes. 1st. Those in which the resistance to motion is furnished solely or mainly by shortening of the extra-articular tissues. 2nd. Those in which, in addition, more or less considerable changes in form and relation of parts of the articulation, in consequence of subluxation or partial dislocation of the articulating ends of bones, has occurred. 3rd. Those in which more or less considerable changes within the joint have occurred, *viz.* transformation

of the synovial surface, vascular adhesions, fibrous adhesions, erosion of cartilage or of bone, mineral or bony deposits. 4th. Absolute osseous ankylosis.

The first class of cases is common. We have met with numerous instances of knee and elbow-joint contraction, induced respectively by severe, deeply-extending burns, by phlegmonous erysipelas, by 'swelled leg,' in which the history of the case, the state of obvious contraction and adhesion of the extra-articular tissues, together with the absence of displacement or deformity of the articular extremities of the bones, left no doubt in our minds that the articular surfaces, notwithstanding the paucity of motion, or its entire absence, were free from organic change. In these cases, restoration of form, and often an almost complete recovery of spontaneous, *i.e.* voluntary movement, may be effected without difficulty.

The cases in which more or less luxation of bones exists demand greater attention during treatment than those in which abnormal flexion alone exists. The subluxation is often accompanied with abduction of the tibia and consequent genu valgum (see section on this knee deformity).

The third class of cases includes some which have had a similar origin to those of the first category, but in which the injury or inflammation has extended to the interior of the joint, or at least has involved the capsular ligament. In these cases, deep, retracted, indented cicatrices, and bands of indurated adventitious tissue, penetrating, it may be presumed, into the hollows and sinuosities of the ends of the bones, even if all happen to be exterior to the articulation, tell of exposure of the synovial membrane so near to the disease, that it is improbable that it will have escaped. These cases admit of rectification of position, and commonly some degree of voluntary motion follows. The bulk of this class consists of cases resulting from strumous synovitis (?) and diseases of the articular extremities, rheumatic and gouty contractions, and distortions from accidental violence.

The strumous distortions of the knee usually present considerable mobility within a limited range, with much deformity and prominence of the internal condyle from subluxation, inversion, and from wasting of the member above and below the articulation. They are usually straightened without any great difficulty, although much prominence of the condyles and displacement may remain unless guarded against. Partial mobility is usually recovered.

The rheumatic cases which apply for orthopædic relief are principally of two kinds, those in which 'chronic rheumatic arthritis' subsists, and those rarer instances of acute articular inflammation excited by exposure to cold during gonorrhœa, child-bed, or an early stage of lactation. In the first kind, during the comparatively early stage, much intra-articular fluid secretion and free mobility within a certain range remain. At a later stage, in proportion to the development of gelatinous and vascular adhesions and mineral deposit, the movement becomes more limited. In ordinary rheumatism, true ankylosis does not occur. We have been long accustomed to attempt, by gentle manipulations and gentle but firm employment of mechanical contrivances, to restore these limbs to greater usefulness as regards movement and symmetry. We have succeeded in obtaining the latter, but not the former desideratum. In fact, as might be inferred from pathology, the benefit of orthopædic treatment is in the inverse proportion to the anatomical degeneration which the rheumatic joint has undergone.

In the second kind of rheumatic cases of partial ankylosis, those which have commenced with very acute affection of one joint, most often the knee, the loss of motion occurs rapidly, and is frequently complete. It seems, in these cases, that an acute destruction of the synovial surface, with rapid exudation of mortar-like plastic material, takes place, causing firm agglutination of the ends of the bones.

Tact in the examination will usually show that absolute immobility of the knee, from whatever cause the ankylosis has proceeded, does not exist. The joint is movable when a gentle and unexpected effort to bend or straighten the limb produces a sharp pain through it. We deduce some favourable conclusions as to the state of the joint if we find the patella movable. This bone may sometimes be moved upon its horizontal axis when no motion is perceived upon the perpendicular one, and

when no flexion or extension of the knee can be effected by ordinary handling of the joint.

Articular rheumatism, acute and chronic, usually leaves the synovial membrane intact, no deformity, as a rule, remains, the exception being in the knee and ankle; here the weight of the body comes more mischievously into play than elsewhere, and sometimes gives rise to a rheumatic genu valgum, and in-ankle or flat-foot.

Many rheumatic contractions, those which are the least amenable to treatment, belong to the peculiar form of the disease denominated 'chronic rheumatic arthritis' by Adams of Dublin, the 'rheumatoid arthritis' of Garrod.

In reference to treatment and prognosis, a correct judgment of the condition of a joint contracted from disease may be formed from the history and the external appearance, aided by careful manual examination. In the hip, the diagnosis is sometimes more difficult, because the history communicated may be fallacious in consequence of the greater liability to errors in diagnosis during the first stage of disorder in and around this articulation. Hip-contractions occur in which the primary hip-affection had been originally 'sciatica,' muscular and fascial rheumatism of the bulk of the muscles of the hip and loin, or one of the forms of rheumatism of the joint itself, or 'morbus coxæ,' or the result of accident. To these causes of hip-contraction, which are not always diagnosed, we may add the peculiarly grave intra- and extra-articular exudation which occasionally occurs at the close of malignant scarlatina, and the less serious persistent drawing up of the thighs which occurs (without pyæmia) during a tedious confinement to bed from fevers and phlegmasiæ, especially in persons whose growth is not complete. We have also met with severe rigid hip-contraction, with pain and wasting, which had commenced during pregnancy from uterine influences; also after childbirth from puerperal disturbance; and in unimpregnated, as well as in unmarried women, even from great fecal accumulation in the intestines. Whilst reminding the surgeon of the various causes of persistent hip-contraction, we may complete the list by adding congenital and neo-natal contractions and luxations, paralytic and spasmodic contractures, some of these being hysterical, and some very grave affections, proceeding from disease of the brain or spinal cord, sometimes co-existing with angular spinal curvature. These numerous causes of hip-contraction are not enumerated as if they were so many pitfalls to the surgeon; but in order that, knowing what may have produced a given contraction, the young surgeon may be forearmed for diagnosis and successful treatment.

Treatment of partial and complete ankylosis.—The several forms of contracted joints of the extremities above enumerated admit of four modes of treatment: 1st. Mechanical extension, including manipulations and shampooing. 2nd. Tenotomy, succeeded by gentle, gradual mechanical extension. 3rd. Violent extension under the anæsthetic influence of chloroform, sometimes preceded by tenotomy. 4th. Osteotomy.

The majority of joints affected with incomplete ankylosis, even the knee, elbow, or hip, still more the smaller articulations, and even after three or four years' duration of the contraction, admit of as full and prompt restoration by gradual, gentle employment of mechanical extension as by either of the remaining modes of treatment above indicated, with the advantage of the treatment being conducted without pain, suffering of any kind, or confinement to the house. In severe knee cases of many years' duration, subcutaneous division of the hamstring muscles may advantageously precede the mechanical treatment, the surgeon bearing in mind that here, as in other distortions, success depends more upon the manner in which the mechanical treatment is conducted than upon operative interference (see p. 268). In a small proportion of cases, those in which apparent total immobility exists, or in which it is obvious that partial calcareous deposit has taken place, violent extension, with the aid of chloroform or ether, may be employed.

Mechanical extension of partially ankylosed joints.—Little actual apparent power is required to overcome the most rigid cases. The first condition of success is the correct adaptation of the appropriate apparatus to the size and natural move-

ments of the part, and to the departures of the limb from the natural form and direction, remembering what has been said (p. 267) as to the combination of genu valgum with abnormal flexion from disease. When practicable, the apparatus should only limit the movement of the affected joint towards the contracted side, *i.e.* it should not immovably fix the part in every direction, but should leave some 'play' to the limb in the direction which it is wished the part should take. No curable ankylosis, free from bony union, can resist gradual, gentle pressure; we only resort to tenotomy in addition to mechanical extension for the purpose of saving time. A little consideration will explain how apparently slight continued pressure can effect so great a result as the straightening of a knee contracted for more than twenty years from former articular disease or injury. The uninitiated surgeon is accustomed to regard such a joint as 'nearly ankylosed;' perhaps he does not reflect that if bony union has not taken place, the opposing structures are 'soft parts,' *i.e.* shortened muscles, ligaments, fasciæ, cutaneous textures, and cicatrices, all liable to yield to steady pressure. It is probable that as soon as this gentle pressure is applied, the contracted muscles, shortened merely from position and repose, *not being spasmodically affected*, resist elongation, but they speedily tire, and give up the unequal struggle; the non-muscular parts, however dense they may be, probably undergo some change of vascularity, some interstitial change in their nutrition as a consequence of the *gentle violence* they undergo through which their mechanical power of resistance is diminished. An increase of temperature and of bulk of the part undergoing too rapid mechanical extension is usually perceived, which we believe to be due to increased flow of blood consequent upon the stimulus of the state of tension in which the resisting tissues are maintained. This augmented flow of blood is unaccompanied by inflammation or even by pain when the part is at rest. Such appears to be the process in the structures on the contracted side of the member. The treatment probably receives aid from the muscles on the uncontracted side. The direction of the distortion was originally determined by the stronger set of muscles, or by those most advantageously situated, having overpowered the weaker set. When the contracted muscles yield in their turn to the mechanical instrument, the muscles situated on the uncontracted side tend to recover their lost sphere of action, and assist replacement.

At the knee-joint, the thigh and leg each offer a great length of leverage, advantageous for successful treatment by mechanical extension; and consequently we have met with no partially ankylosed knee which has not been straightened and rendered fit for use without the aid of tenotomy or chloroform in a period varying from one to three months.

The anatomical relations of the hip-joint render it, as already mentioned, less favourable for orthopædic treatment than any of the ginglymoid articulations. We may mention, in illustration, that in an instance of uniform fibrous and vascular membranous adhesion of the head of the femur within the acetabulum after death, the partially ankylosed pelvis and thigh having been removed from the body, we were unable to extend the hip by any power we could exert with our hands, until the capsular ligament and some of the adhesions within the acetabulum had been severed with the knife. The same kind of adhesions in a knee would have yielded to the power fruitlessly employed at the hip.

The continued attention of orthopædic practitioners who, during the last five-and-thirty years, have trodden in the footsteps of Scarpa and Stromeyer, bringing pathological and anatomical knowledge with experience to the aid of the instrument-maker, has revolutionised, simplified, and thus far perfected orthopædic apparatus. When practicable, elaborate instruments should be avoided. In numerous instances, as in congenital club-foot of adolescents, in considerable knee-contractions, and subluxation, the necessity of well fixing one part whilst another is acted upon, or the complicated character of the deformity itself, entails corresponding need of an elaborate contrivance.

Different mechanical forces are employed—the lever, the screw, and the spring; the last two often resolvable into the lever, screws and springs being employed to

modify the action of the lever. The discussion of the relative advantage of the different modes of applying these forces would lead us away from our immediate object.

It should be borne in mind during the employment of these forces in orthopædic apparatus, and especially in the use of the screw, that it is available less as a means of abruptly forcing the deformed parts into their natural position than as an adjusting contrivance. In any case in which the screw is *forcibly* employed, excoriation, sloughing, or intolerable pain, will inevitably result. In some *patient* individuals, vesication, and even superficial sloughs, may be induced over projecting bones without complaint of pain—an urgent reason for anxious examination of a part subjected to pressure, especially by the inexperienced orthopædist. Large sloughs are more than inexcusable.

Every apparatus should be padded, so as to avoid pressure upon prominent points of the bone, and adapted to each individual case. The orthopædic apparatus, like that for a fractured limb, should compress the part in its circumference as little as possible, and never tightly encircle it. It should act gradually, *in proportion as the deformity itself changes in degree*. A simply contracted knee resting upon its posterior aspect in an apparatus slightly straighter than itself, tends by its own weight to regain a straighter position.

The greater number of contracted joints, when not affected with bony ankylosis, if left to themselves, may be regarded as contracting joints; for the contracting process is ever progressing until it attains the maximum.

At the outset, the surgeon should be content almost simply to apply the instrument to the deformity, and not to apply the deformity to the instrument, as is too often attempted by novices. In this gentle manner of proceeding, the first difficulty in the treatment of every case of deformity is overcome,—the patient suffers nothing from the attempt to straighten the part; the simple inconvenience of wearing an apparatus, the irksomeness attendant upon necessary confinement of the affected part in an unfamiliar instrument, is his only trouble, and one which is speedily, in a day or two, overcome. Having once applied a well-fitting instrument, the screws or straps by which it is adjusted to the now improving member require to be advanced or tightened as opportunity offers. An impatient advance of the pressure will, by production of pain, and necessity for relaxation of the instrument, occasion loss of time. The principle of action in the progress of mechanical treatment should be that of never advancing too rapidly, so as to risk the necessity of receding. By gentle steady advance, the patient's confidence, so essential to prompt recovery, remains undiminished. By subjecting the member to no greater pressure than can be easily borne, no temptation to loosening the apparatus is afforded to the timid, and no risk is incurred of occasioning excoriation or inflammation in individuals possessing greater endurance, or in young children, whose cries might by mistake be attributed to other causes. The surgeon, or a trustworthy attendant, must take due precautions that the patient does not play 'fast and loose' with the apparatus. In this manner, in suitable cases, the opposition offered to restoration by fasciæ, tendons, ligaments, and ill direction of articular surfaces, apparently irresistible, may be removed.

In the choice of mechanical apparatus the surgeon should also be guided by that principle which actuates him in the selection of therapeutic agents in any internal or external disease, viz. the use of that means the action of which he best understands, or in the use of which he has had most experience. A common splint, properly applied, will effect more benefit than an instrument of greater pretension indifferently managed.

We have straightened in a few months, or within a year or two, many rigid partially ankylosed hips, believed at first to be true ankylosis, without confinement in lusty adolescents, in whom the thigh had been several years bent more than a right angle, with corresponding great lordosis, the limb afterwards touching the ground with the help of a raised shoe, mainly needed on account of the wasting of the limb caused by the previous disease.

Much harm will result, in many deformities, from the practice unwisely pursued of keeping a deformed part many weeks in succession in an apparatus without the removal so necessary for the purposes of cleanliness and readjustment. Among the evil consequences of too long retention of instruments, often combined with unsuspected excessive pressure, the author has witnessed a degree of rigidity of the ankle, not previously rigid, which has required weeks of manipulations and stretchings, before the natural movements have been possible. Sometimes, indeed, as in the elbow, restoration of motion of an articulation has been rendered impossible.

The slighter the deformity, the more necessary is frequent removal of the apparatus, because by removal and appropriate manipulations we insure retention of mobility. In severe cases, in which we expect only to effect straightening, and do not anticipate restoration of mobility, frequent removal of the apparatus is unnecessary; for too frequent removal may be hurtful, by allowing the recently elongated tissues to recontract during the time the apparatus is removed from the part.

Division of the hamstring muscles.—In a limited number of knee-contractures from disease and accident, section of hamstring muscles may be required as a preliminary to gradual mechanical extension, or to abrupt violent extension under chloroform. In all cases after tenotomy, extension, whether gradual or abrupt, should be delayed until the healing of the punctures in the integuments. In the knee this healing is seldom complete until four or five days after the operation. The following rules may be given for severing the hamstring tendons: Place the patient in the prone position, and let an assistant make firm extension upon the joint, or, when anæsthesia is not employed, desire the patient to endeavour to bend the knee, by either of which means the tendons will be rendered prominent. In general follow the directions laid down for the division of the tendo Achillis (p. 238). In severing the tendon of the biceps femoris, insert the tenotome in the adult an inch above the apparent point of contact of the tendon with the fibula, remembering the proximity of the external popliteal nerve, and keeping, therefore, the tenotome close to the tendon. The semi-tendinosus being very superficial is readily severed by a puncture, where it springs up most prominently; the semi-membranosus being more bulky and fleshy, as well as more deeply seated, requires a larger sweep of the end of the tenotome. It is scarcely necessary to recommend caution as to the important nervous, arterial, and venous structures of the popliteal region. After section of the inner hamstrings, the pressure of the assistant's hands upon the limb being continued, bands of fascia and nerves make themselves prominently felt in the ham. Troublesome numbness of the calf, and unusual pain during extension, has followed the unnecessary division of these structures. It is desirable to apply promptly a pledget of lint and suitable pressure by a bandage over the punctures, to prevent oozing of blood into the areolar tissue of the ham, which affords an inconvenient nidus for suppuration. By adopting this immediate covering and pressure over the puncture, we have never witnessed delay in healing beyond four or five days, in ordinary moderate temperature. Very cold weather may cause tenotomay punctures in limbs of weak circulation to appear, at the end of several days, as if they had been effected an hour previously, no attempt at adhesion being made. It is therefore proper in cold weather to envelop the limb in flannel, and assist the reparative powers of the patient by generous diet.

Forcible subcutaneous separation of the tibia and femur in true bony ankylosis of the knee-joint.—This operation, originally proposed and carried out successfully by Langenbeck, and Gross of Philadelphia, was first performed in this country with some modifications by Mr. Little at the London Hospital, and has since been performed successfully by many surgeons. It has, as we surmised in the last edition, become a standard operation in surgery. The operation consists in making a small incision in the integuments and fibrous tissues at the side of the articulation, parallel to the plane of the natural articulating surface of the tibia. The length of this incision should correspond with the width of a narrow, sharp-cutting, well-tempered chisel or osteotome, bevelled on both sides, as recommended by Macewen, so as to

ensure its travelling in the required direction, say two or three lines in width, which being driven in different directions between the ends of the femur and tibia, which are united by osseous material, so effectually weakens the connection between the adherent surfaces, that straightening and bending of the limb can, with the exercise of 'gentle violence' with the hands, be readily effected. When the surgeon remembers that the *joint* has been destroyed by the diseased process which produced the bony anchylosis, he will not be surprised to learn that this surgical subcutaneous chiselling asunder of bones is not followed by any of the serious consequences known to follow, occasionally, wounds of the joint, and that with or without simultaneous section of knee tendons, as may appear requisite, the limb may be placed in the desired curative position. Osteotomy for relief of knees affected with *bony* anchylosis in a bent position, is in every respect preferable to the operation of knee resection, when it has been performed for mere anchylosis. (Section on 'Osteotomy' in the essay on the SURGICAL DISEASES OF CHILDHOOD, VOL. III.)

Division of muscles in the vicinity of the hip joint.—Though in hip contractures the majority of the muscles proceeding from the pelvis on the flexed side of the part are contracted, experience teaches that few require operative interference. We have many times severed the origins of the adductor longus, adductor brevis, and pectineus, the tensor vaginæ femoris, and the superior origin of the rectus femoris. But of late years we have commonly restricted the operation to the tendon of the adductor longus, for the relief of tense abnormal approximation of the thighs, in cases of general spastic rigidity of the lower extremities. The adductor longus, from its position, exerts a relatively greater influence in morbidly adducting the thighs than other muscles. Its division is a satisfactory starting-point for subsequent benefit from mechanical exercises and use. It is effected according to the general principles of tenotomy, and requires no particular description.

Section of the tensor vaginæ femoris and rectus is suggested in certain cases of paralytic contracture of the hip, in which atony of the adductors of the thigh exists, a state of things opposite to the last-mentioned kind of case. Here the thigh is drawn from its fellow, the trunk tending to fall to the ground, as it were, between the thighs. Where contraction of these muscles exists, the paralysis of the adductors and other muscles of the hip (peræ and glutei) is usually so considerable, that little radical good results from the operation. It should, therefore, as a rule, be superseded by manipulations, frictions, and mechanical appliances.

Division of the flexor tendons of the fingers and toes.—The phalanges, when contracted from articular complaints, require treatment similar to that of the larger articulations. Commonly it is the flexor tendon which is implicated. Enough has been stated concerning the large ginglymoid articulations to render many details of treatment of these small articulations unnecessary. In operating on the fingers, we have to consider beforehand whether the articular disease has left the joint in a condition to resume its function as to movement; for if we may not expect to recover mobility, a straightened finger is not preferable to one partly bent. The contracted flexor tendons of the fingers should not be severed opposite the phalanges, for as a rule adhesion to the sheath, and often a stiff, extended, useless finger results. See section on 'PALMAR AND FINGER CONTRACTION' (p. 254).

In the foot, the most frequent affections of the toes for which surgeons are consulted are those resulting from improper shoes worn during the growing period of the foot—in childhood and adolescence. The great toe is often thrust outwardly, and overlaps the next toe, the metatarsophalangeal articulation being inflamed and ultimately deteriorated as to the normal condition of the articular surface, with consequent impairment of mobility and very troublesome lameness. The joint is inclined to stiffen in the extended position after subsidence of the irritation or inflammation, the individual being prevented standing tip-toe, or ascending a hill without pain or inconvenience. This condition of things may, before and about puberty, be remedied by rest and suitable topical applications, followed by manipulations; the interposition of a partition between the toes, so as to keep the great toe

in a proper line with the margin of the foot; and the temporary use of a suitably wide shoe. In long-standing cases, in which the extensor tendon of the great toe becomes rigidly contracted and structurally shortened, and has become dragged outwardly away from its normal situation above and parallel to the metatarsophalangeal articulation, the section of this tendon may afford relief.

Another common troublesome defect in the toes, similarly produced, though sometimes hereditary, is fixed flexion of the second toe, the 'hammer toe.' In children under the age of eight or ten years, this defect can usually be remedied by light gentle bandaging (not tight) of the part, upon a padded whalebone splint, night and day, for a few weeks. In older subjects, and in peculiarly rigid cases, section of the flexor tendon, opposite the first phalanx, followed by bandaging on the splint, is a prompt and certain means of cure. It is true that the interphalangeal joints remain straight and immovable. This is in the toes an advantage, as it prevents the possibility of return of the distortion, and it does not interfere with walking.

The little toe is often extended upon the metatarsus, or thrust laterally and inwardly and sufficiently prominent to become continually a source of pain and irritation from the shoe. This also is often a congenital affection. Division of the extensor tendon and bandaging usually afford relief. When the shape of the articular surfaces of the toe and corresponding metatarsal bone are much altered, removal of the toe will alone afford permanent relief.

The toes, and particularly the great toe, are often contracted in cases of varus, congenital and acquired. These contractions are relieved by the means taken to cure the talipes, and sometimes by gradually improving their position with suitable bandages. In other instances, in adolescents and adults, owing to the pain and lameness induced by corns on the prominent parts of the toes, the joints of which had become firmly contracted, the first phalanges in the *extended* position, the terminal phalanges in the *fixed* position, we have found it necessary for entire relief to sever the whole of the flexor and extensor tendons, followed, after healing of the puncture, by bandaging the toes on straight splints for a few days. These cases have shown no disposition to return. We may mention that we have more than once been called upon to do this wholesale toe tenotomy upon three generations, during their respective stages of adolescence. We have never been able satisfactorily to make out to what extent, if any, the contraction was due in each generation to the wearing of unduly small and short boots and shoes. We believe that such cases are due to hereditary predisposition analogous to certain finger contractions (p. 253), hastened on and intensified by the toes being deprived of their natural play and mobility in the cramped space allotted to them.

Forcible extension.—Under the head of *manipulations* and stretchings, the value of gentle employment of pressure and movements with the hands (passive exercise), both as a means of curing slight deformities, and as an important auxiliary to other methods of treatment, has been shown. If a larger measure of pressure or force be used with the hands, the treatment becomes that denominated *violent extension*. Here, as elsewhere, it is difficult to draw an arbitrary line, and say where gentle manipulation ends, and violent extension begins. In the practice of manipulations, the competent operator may frequently avail himself of the smaller degree of sensitiveness displayed by some patients, or of the momentary abstraction of the patient's volition from the muscles (a circumstance instantly felt by the hand of the operator), and apply an amount of force which approximates to, or may be considered as, violent extension. But *violent* extension with the hands is rarely efficacious in the removal of considerable contraction and deformity, especially in full-grown persons, because either the pain produced is intolerable, or the voluntary resistance offered by the muscles of the patient exceeds that at the command of the operator; a struggle is maintained between the patient's muscles and the surgeon or rubber, in which the latter is commonly not victorious.

Through the inability of one person to effect, with any effort of his will, an extension forcible enough to overcome severe contraction, violent *sudden* extension,

by means of the combined strength of several assistants, or by means of powerful screws, brought suddenly into action, was proposed and carried out, with varying success and misfortune, by Louvrier, Dieffenbach, Delore, and others. In the less severe cases of deformity, those indeed which are curable by gentler means, without longer duration of treatment, the parts were suddenly straightened by violent extension, without ultimately mischievous results, and the expected benefit was obtained. But in severer cases of deformity of many years' existence, in which organic changes of greater magnitude had taken place, as in severe knee-anchylosis from extensive suppuration about the articulation, with necrosis, the violent separation of adhesions, and snapping asunder of bony deposits in the popliteal space and elsewhere, were accompanied with laceration of blood-vessels and nerves, fractures of the bones themselves, and consequent inflammation, suppuration, and even mortification, of the member.

We are indebted to Langenbeck¹ for the aid to, and lessened danger of, forcible extension, afforded by anæsthesia. During anæsthesia the two great obstacles to the employment of force adequate to straighten or bend a contracted limb, namely, pain and voluntary muscular resistance, are removed. As soon as these impediments disappear, the hand of the single operator, and his single mind, applied to the parts, encounter the physical resistance only of the deformed parts; comparatively gentle manipulations now acquaint him with the nature and amount of difficulty, he can feel his way in the application of greater force; can feel and perceive the resistance of parts successfully overcome, in an anatomical order; if greater rigidity still oppose, a few movements of the joint backwards and forwards prepare the way for a more extensive yielding: and often the practitioner has the satisfaction of being able thus to effect every natural movement of the joint. The possession by the surgeon of this prerogative, the handling of a limb under anæsthesia, needs reflection and great caution against abuse of power.

Chloroformisation, with manipulations, and the use of a certain degree of force, may be of service as a means of diagnosis. By it the practitioner is enabled, in some degree, to ascertain what proportion of the deformity is due to shortening of soft parts, how much mischief the articular surfaces have undergone, and what amount of restoration is practicable.

After straightening or bending of the limb, as the case may have required, by means of this forcible procedure, the part should be lightly secured in a retentive instrument, or upon a common splint, and adjusted so as to maintain a position more favourable than that in which the limb was before the operation, though it may not always be possible to keep it in the new position, i.e. the entirely straight or bent position into which the hands of the surgeon may have brought it. For as soon as the effect of the chloroform disappears, the patient arouses to the conviction of the violence which may have been employed; the part may be acutely painful, and incapable of sustaining the pressure of a tight bandage or ligature.

We usually content ourselves with the increased knowledge obtained of the nature of the case, with the satisfaction of knowing that the part can be improved in form and function, and as the resisting parts have once yielded, that they will afterwards oppose less resistance to replacement; whether the means subsequently employed should be simple manipulations, the use of mechanical apparatus, or the once or twice only repeated administrations of chloroform, and less forcible extension. The surgeon who attempts the forcible binding down of a long deformed limb immediately after forcible extension betrays a lamentable indifference to the patient's sensations, and an equal ignorance of the pathological condition of the parts in the immediate vicinity and within the diseased articulation. Although the muscular structures may have yielded under chloroform, and indurated fasciæ and old adhesions may have been overcome by stretching and tearing, it should be remembered that much adaptation on the part of nerves, blood-vessels, and absorbents to the altered

¹ *Commentatio de Contractura et Ankylosi Genu, nova methodo violentie extensionis opusculum*. Berolini, 1850.

position of the structures needs to be accomplished. We find that, by taking moderate means of retaining as much improvement after the forcible extension as can be borne by the sufferer, by the unsparing use of lotions of spirit or by ice applications, and by the internal or endermic use of morphia, inflammation of joints thus straightened has been averted.

It is perhaps not superfluous to remark, that the use of forcible extension is less defensible in cases of recent disease of articulations than even other active attempts to restore the form in such cases. In a diseased joint the practitioner has to note not only the local disorder, but also the general condition, of which the local affection is but one manifestation. When the surgeon, with ability and experience, has cured the local disorder, *i.e.* removed the inflammation, healed the ulcerated or suppurating parts, or effected subsidence of pain, heat, and tumefaction, the consequences of the diseased action, contracture and rigidity only remaining, he has not necessarily cured, by internal and therapeutic measures, the morbid constitutional state. This often slumbers after subsidence of the local disease; and he should pause ere he too hastily undertakes the restoration of form and movements by forcible extension under chloroform, or by other active measures, and thus incautiously evoke a renewal of local disorder.

These views were enunciated¹ some years ago by the author, perhaps with more leaning to the employment of forcible extension. It will be found that violent extension is necessary in a relatively small number of cases provided gentler means are suitably carried out. Orthopædy is capable of curing all those contractions in which the innervation is not hopelessly disturbed (severe paralysis and spasm), and those in which the synovial surfaces, cartilages, and articular extremities of the bones are not disorganised from disease. When we cannot hope to do more than straighten the limb, as in long-standing hip and knee contractions from articular diseases, rational violent extension under ætherisation is most opportune as a means of obtaining a more useful position of the member.

The expectations of surgeons some years ago of the benefit likely to result from operative interference in cases of partial hip ankylosis, so as to produce a new or artificial joint, have not been verified. Excision of the head of the femur, owing to inability to deal effectually with the co-existent disease of the acetabulum, has been less successful than elsewhere. In long-standing hip ankylosis, be it false or true, if we should be unable to straighten the member by gradual mechanical treatment, or by forcible manipulation under chloroform, there is one resource available, that of severing the bone subcutaneously below the trochanter, where it most nearly approaches the surface; or as recommended by us in the last edition of this work; or as carried out by W. Adams, above the trochanter. The late Mr. Maunder, following the example of Mr. L. S. Little, had excellent results at the hip from division of the femur with the chisel and mallet (see the description of the various operations of osteotomy appended to the section on Rickets in the essay on DISEASES OF CHILDHOOD, vol. iii.)

In a few cases at the other extremity of the pathological scale, in which the will alone, or timidity, or the peculiar abnormal state of the system exists which is met with occasionally in young persons of both sexes, in whom, in consequence of slight injury, a limb remains stiff in the straight or bent position (emotional or ideal paralysis), the part is relaxed under ætherisation, and the contracture is often by this means promptly and permanently cured. True hysterical contractures yield with equal facility during the anæsthetic state; but they usually return when the effect of the chloroform has passed off. In some of the severest hysterical cases the author has met with, recovery has taken place after the lapse of a few months, or a year or two, either spontaneously, or from the effect of altered dietetic, social, or climatic influences (p. 259).

The following case well illustrates the diagnostic and curative value of judicious investigation under anæsthesia :—

¹ *Treatise on Deformities of the Human Frame.* 1853.

December, 1854. Master C —, aged 12, an intelligent lad, was brought on account of stiff straight knee. Six weeks previously he fell whilst running, and was supposed to have wrenched or struck his knee against a projecting ledge of stone. After the accident he hobbled half a mile, and continued very lame, the knee immovably stiff. On examination we found neither inflammation nor distortion, or other cause of stiffness. The force of 'position fixe' was so considerable that we could make no impression upon it with our unassisted hands. He did not appear unduly nervous, and as it was holiday time it was unlikely that he had any inducement to malingering. We suspected dislocation of articular cartilage. Exploration under anæsthesia was undertaken. During inhalation the leg projected stiff over the side of the couch. Gradually, as the anæsthetic took effect, the weight of the foot and leg caused bending of the knee. No further treatment was needed; the knee continued flexible and fit for immediate use.

W. J. LITTLE, 1882.

DISEASES OF THE BONES.

DISEASES of the bones may be conveniently divided into the following classes :—
First, inflammation and its consequences : under which head it is proposed to include the varieties of the inflammatory process, which have received the names of periostitis, osteitis, and osteo-myelitis ; and, as consequences of these, all the numerous conditions which have been confounded together under the common but vague designation of caries, the various forms of suppuration in bone, the varieties of necrosis, its effects, and those processes of repair which result in permanent modification of the structure and form of the organ. The *second* class will include the specific diseases, which occur either as modifications of the inflammatory process—syphilis, scrofula, and rheumatism in bone—or as constitutional conditions leading to changes in the bony structure ; such are mollities ossium, rickets,¹ and cancer. The *third* division will comprise a description of the various new formations found in the osseous system, and which are not dependent on any of the known constitutional cachexiæ. The *fourth* will treat of atrophy and hypertrophy, properly so called, i.e. uncomplicated by inflammation.

SIMPLE INFLAMMATION AND ITS CONSEQUENCES.

Inflammation of bone differs from inflammation of soft parts, not in its essential, but in its accidental features ; the inflammatory process is the same, but the conditions or circumstances are different, and hence arise diversities in rate of progress, in external appearance, and in other symptoms ; diversities which, although they are not really essential, yet cause striking differences to ordinary observation, and have led to the designation of the results of inflammation in bone by names differing from those which are used for the same changes in soft parts. This difference in nomenclature, though it might arise in mistake, at a time when necrosis was thought to be something essentially different from gangrene, and caries a disease which had little in common with ulceration, is yet hardly to be regretted, since the diseases of bone, though pathologically identical, are practically very different from those of soft parts ; and it is convenient to have separate names for things which require very different treatment, and entail a very different amount of danger.

If the reader will consult the essay on INFLAMMATION, he will find abundant information on the early steps of that process. These affections are identical in bone and in soft parts ; in fact, they can occur only in the soft parts of bones, since the mere inorganic matter, which, involved in the convolutions of a cellulo-fibrous and vascular network, constitutes a bone, can itself be the seat of no vital actions, but must obey the movements impressed upon it by the living textures around.

The essential elements of the inflammatory process in bone appear to be the proliferation of the soft structures, accompanied by the multiplication and enlargement of the cells which those structures contain, and by an increase in the quantity (possibly also by a change in the quality) of the fluid by which the organic elements of the bone are permeated and nourished. This increased growth of the soft structures causes them to press upon and eat into the inorganic skeleton, and it is the opinion of some pathologists (as Rindfleisch) that the inflammatory fluid acts as a direct solvent on the salts of the bone. Hence, on microscopical examination, there

¹ The subject of Rickets, however, will not be found here, as it has been thought better to refer it to the SURGERY OF CHILDHOOD.

will be found, between the trabeculæ of the bone, a fungous mass somewhat analogous to granulations, and often called by that name, in which may be distinguished the altered cells of the part, frequently in the form of those giant-cells which Kölliker called 'osteoclasts,' when occurring in the growing bone, from their supposed function of destroying or absorbing the old bone. The projection of these granulations against the trabeculæ hollows the latter out into irregular spaces, called 'Howship's lacunæ,' just as in the normal growth of a young bone the central space is enlarged by absorption around the growing medulla. The medullary tissue of the inflamed bone is also swollen, granulating, and often permeated with pus. The lacunæ break down, and often break into each other, so as to present the appearance of a canal, a phenomenon described by Rindfleisch as the 'canalization' of bone. All this leaves the bone, of course, much more fragile, light, and juicy, than natural. To this early stage succeeds one in which the presence of suppuration is more decided, and the erosion of the internal spaces of the bone more advanced—and now the bone is said to be carious. All this refers to the inflammatory process when most acute, and therefore most easily perceptible. There is no reason to think that chronic inflammation differs in its essential features; but it is hardly possible to find a bone in the early stage of chronic inflammation.

Such are the earliest changes in the minute structure and consistence of inflamed bone. The changes which take place in its rough anatomy may be thus described. If a bone be examined at an early period of inflammation (the ordinary and most accessible instance is the stump of the bone in an amputation fatal, say, three weeks after the operation),¹ the periosteum will be found somewhat thickened, vascular, and not so closely connected to the bone as usual.² If the periosteum be stripped off, the bone is seen to be irregularly vascular, some portions of it having a slightly red tint, and contrasting with the healthy white colour of the rest of the bone. This red tint is evidently caused by the enlargement of the vessels which pass from the periosteum into the bone; and if a magnifying glass be used, the increased size of the vascular apertures is easily proved, while if pressure be made on the surface of the bone, drops of blood will frequently ooze from the mouths of the enlarged vessels, proving their increase in size, as well as the loss of consistence in the outer hard wall of the bone. At the same time there will be found, in all probability, on some other part of the surface, more or less deposit of osseous matter, which, with the partial separation of the periosteum above mentioned, testifies to the fact of effusion from the vessels of that membrane. In these simple cases of injury the deeper parts of the bone will probably be unaffected; but should this not be the case, *i.e.* should inflammation have also attacked the membrane lining the medullary cavity and cancelli, that membrane will be found in a condition essentially analogous to that of the periosteum, although the different situation of the medullary membrane, and the great quantity of fat and other loose tissues among which its vessels run, will somewhat modify the external appearances. If, however, these appearances be minutely investigated, they will be reduced to, increase in the number and size of the vessels, and effusion of blood, lymph, or pus, according to circumstances. The thickening both of the periosteum and of the medullary membrane is sometimes considerable. The former membrane is, of course, more frequently found thickened than the latter; but preparations showing the participation of the medullary membrane in inflammation of the bone, and the identity of its appearance with that of the thickened periosteum, are not wanting.³

Thus we see that when inflammation commences, as it usually does, on the surface of a bone, whether periosteal or endosteal, its primary symptom is increase in

¹ In such a specimen the periosteum will generally be sound stripped off from a small ring at the lower end of the bone, and this part will perhaps be dead or about to die; but as this feature is accidental, it will not be further noticed.

² Hunter has put up (Mus. Coll. of Surg. No. 656) 'A preparation of a femur, which was amputated, with the periosteum separated; to show how clear the periosteum separates from the bones in inflammation; a fact almost always observable after amputation.'

³ One of the most striking preparations of this kind is in the Museum of St. Bartholomew's Hospital—a humerus; series i. 207.

the size (and perhaps number) of the capillary vessels, or vascular spaces, and effusion of blood or lymph. The primary effects of inflammation in the central parts of the compact tissue are similar to the above; though here, from the different circumstances in which the vessels are placed, this similarity has been less distinctly perceived; and from the slowness with which all changes go on in the compact tissue, opportunities rarely occur of comparing the different parts of the same bone with each other. The first change is the enlargement of the vessels which run in the Haversian canals; but effusion is a much later phenomenon, and is preceded by the absorption of the bony tissue which adjoins the enlarged vessels; so that in microscopical sections of inflamed bone, the Haversian spaces are seen much enlarged, irregular, eroded, and sometimes almost, or quite, communicating with each other. The lacunæ may also be noticed to be densely crowded together, and sometimes the granular matrix of the bone appears more coarse than natural. When this absorption of the walls of the Haversian canals becomes visible to the naked eye, the first change in the rough anatomy of inflamed compact tissue becomes appreciable—that in which spaces are seen in it on section like those in cancellous tissue, so that it is sometimes said to become cancellous. Similar changes occur in the cancellous tissue itself, whereby its cells become much enlarged, and sometimes the whole bone is expanded by the simultaneous yielding of its walls¹.

Into the spaces thus hollowed out in the substance of the bone, or on its surface, by the removal of the earthy matter, the products of inflammation are next secreted. These secretions vary, of course, according to numerous preceding circumstances, *e.g.* the nature of the injury, or other cause of inflammation, the activity of the process, the constitutional condition of the patient, and a thousand others; and so the products of osteitis are divisible into two principal varieties, corresponding to the plastic and aplastic lymph met with in other parts, and leading, the former to the deposition of earthy matter and the formation of new bone, and the latter to suppuration. The former result terminates in hardening, or *sclerosis*, as it is termed; the latter in a variety of conditions: when the suppuration is limited within a cavity in the cancellous tissue, or in the compact tissue rarefied by previous inflammation, *circumscribed abscess* is produced; when the pus extends along the inner surface of the membrane lining the medullary cavity and cancelli, the condition of bone exists which is now usually spoken of as '*osteo-myelitis*,' and which used to be called 'diffused suppuration in bone;' suppuration between the periosteum and bone forms *periosteal abscess*, acute or chronic; and any of these forms of suppuration, when accompanied by the insensible exfoliation of the bone (or its death, and removal in invisible portions), constitutes ulceration of the bone, or *caries*. Lastly, inflammation of the bone sometimes leads to the death of larger portions of its tissue, which are then removed by the process of ulceration, as in soft parts. This constitutes gangrene of bone, or *necrosis*; but as that condition, like other forms of gangrene, is often produced by other causes not inflammatory, the whole subject of necrosis must be treated by itself.

We have now to consider separately the causes, symptoms, and treatment of each of these phases of the inflammatory process; the above being intended only as a kind of ground plan, to mark out the various parts of a rather intricate subject, each of which must be studied in detail.

Ostitis.—Inflammation of bone is excited usually by external violence, or exposure to cold, acting upon a constitution predisposed to the disease. The chief predisposing causes are, the syphilitic or scrofulous taint, rheumatism, and defective nutrition; or these may themselves set up inflammation in any bone, without a distinct exciting cause. From this mode of causation it follows that the bones most liable to inflammation are those most exposed to the action of external agents.

¹ See a description, by the author, of the bones of the lower extremity ten months after excision of the knee, where the superficial laminae of the femur had been so separated from each other by inflammation that the bone cracked under the pressure of the finger (*Path. Soc. Trans.* vol. xii. p. 171).

Hence we see it most frequently in the tibia among the long bones, and in the skull, sternum and ribs among the flat bones. The bones of the foot and hand are also very frequently affected.

Ostitis is a very common affection, although not much recognised; partly because, from the little attention it has received from our older authors, and from the fact that most swellings of bones are regarded as periosteal, we are not much in the habit of looking for it; and partly because its symptoms are at first obscure, and liable to be masked by those of the injury to the soft parts with which it is associated, or of the constitutional affection from which it springs.

The symptoms vary according to the stage of the inflammation. In the first stage, that in which the size of the vessels is increased, and in which absorption is being produced, the disease frequently makes considerable progress without appreciable symptoms.¹ Sooner or later, however, the occurrence of those characteristic dull pains in the bones, exacerbated by changes of weather, increasing in severity during the night, and somewhat resembling the pains of rheumatism, which are described by French writers as '*douleurs ostéocopes*,' draw the attention of the patient to the seat of the disease, and form a valuable guide to the surgeon. If the part be now examined, the probability is that some evidence will be found of inflammation in the tissues surrounding the bone—œdema, redness of the skin, tenderness of the soft parts, or threatening abscess.² The absorption of the earthy material, which accompanies this increased vascularity, manifests its effects upon the bone by a diminution in its consistence, and then the bone becomes at the same time increased in volume and diminished in its resistance to pressure. The former symptom is indeed somewhat delusive, since the apparent increase is often due principally to enlargement of the soft parts. But the swelling of the bone may sometimes be made out very clearly, and is then a valuable indication of the disease. The softening is not generally of much importance as a diagnostic symptom; it rarely affects the whole thickness of a bone, so as to lead to a change in its form, and, when limited to a portion of the surface, cannot be appreciated by the touch, since the inflamed and irritable condition of the soft parts renders the patient unable to bear the necessary pressure.

A singular change, which sometimes follows inflammation of a long bone, is its elongation. Dr. Humphry has laid much stress upon the consequences of diseased conditions of the epiphyseal lines near the ends of long bones, as affecting their subsequent growth.³ It is possible that inflammation of this tissue may have led to the elongation of the bone in some of the cases; as in a tibia from a lad aged eighteen, preserved in the Museum of St. Bartholomew's Hospital, in which the bone has become lengthened, and is curved in order to adapt its length to that of the healthy fibula.

To the stage of absorption and rarefaction succeeds that of effusion and deposit, and as the process be arrested, and resolution occur. The various consequences of suppuration enumerated on the previous page being reserved for subsequent sections, we need now only consider that termination of inflammation of bone in hardening or sclerosis, which corresponds to the inflammatory solidification of parenchymatous organs; and which, when not too extensive, is for practical purposes little less desirable than complete restoration to health. The interstices of the cancellous tissue are filled up at first with lymph, in which ossific matter is afterwards deposited; and then the bone, which, while actively inflamed, had been less dense than in its healthy condition, as

¹ This is true more especially of the earlier stages, but is occasionally observed in all periods of inflammation of bone. Thus large psoas abscesses, connected with extensive erosion of the vertebræ, are found sometimes in patients not of a strumous habit, and who have not been known to present any symptoms of such an affection.

² It has been asserted by Lücke that the tenderness of the bone to percussion may be made use of as a diagnostic sign of the presence of inflammation, and for this purpose he uses a percussion-hammer formed of a whalebone handle with a metal head coated with india-rubber. By comparing the effect of similar blows with the hammer on the bones of the two sides, the fact of increased sensitiveness, and therefore of inflammation in the suspected bone, is to be verified, whilst its exact seat will be fixed by observing the direction and the force of the shocks necessary to elicit the morbid sensation (Lücke, *Archiv. f. Klin. Chir.* vol. xvi.)

³ *Med.-Chir. Trans.* vol. xlv. p. 204.

in fig. 43, becomes hard, heavy, and solid, as in fig. 44; the medullary canal is narrowed or filled up, and the shaft thickened by deposit from the periosteum. Bones thus affected abound in every pathological collection; and it is easy to trace in them many of the appearances of which an explanation has been attempted above—the large size of the vascular apertures, the irregular deposit of bone, both in the centre, in the substance, and on the surface of the shaft, the contraction of the medullary cavity, and usually the increase in size of the nutrient foramina. It will generally, but not always, be noticed that these changes are limited to the shaft of the bone, when it is the part first affected, and that the articular ends escape. The converse is also usually the case; though perhaps the shaft is more prone to become

FIG. 43.—(From a preparation in the Museum of the Royal College of Surgeons, No. 3085, to illustrate the rarefying stage of osteitis.) The tibia in this case weighed 9 ounces.

FIG. 44.—(From a preparation in the Museum of St. George's Hospital, series ii. 19, to illustrate the termination of osteitis in condensation or sclerosis.) The tibia in this case weighed 19 ounces.

involved in the morbid actions of the joint-ends than the joint-ends are in those of the shaft. Thus inflammatory affections may long go on in the shaft of the femur, yet the knee-joint remain unaffected; and, on the other hand, when disease of the joint commences in the articular ends of the bones, the shafts usually are unaffected, and the disease of the bones considered by itself is not so extensive as to contra-indicate excision. To each of these two general rules, however, numerous exceptions will, unfortunately, be met with in practice.

Inflammation of the bone is almost always known, in common parlance (when it is recognised at all), as *periostitis*; but, in truth, periostitis seldom occurs uncomplicated, unless in the course of secondary syphilis;¹ and almost all the cases which pass under that name are really inflammations, more or less extensive, of the bone. Periostitis is a quicker process, and one more under the influence of remedies than

¹ I would refer the reader to the section of Syphilis in Bone for further details on the subject of chronic periostitis.

the other forms of inflammation of bone; but in all the same general course of treatment is indicated, viz. the internal administration of iodide of potassium, and the local application either of iodine or mercurial ointment, or, in the early stage of the disease, of blisters. These measures should be combined with proper position of the affected member, and as much rest as is consistent with attention to the general health. Leeches or cupping will afford relief if the pain be severe. When there is much tension over the bone, sometimes accompanied (especially in the cranium) with intolerable pain, nothing gives such immediate and decided relief as a free and bold incision down to the bone. The distended periosteum is thus relaxed; and in cases of pure periostitis such a measure may of itself almost suffice for the cure of the disease; but its beneficial effects will be decided, though less striking, in cases of

Two drawings from a preparation in St. George's Hospital Museum, to illustrate the ordinary anatomy of periostitis.

FIG. 45.—Periostitis. (Internal view) FIG. 46.—Periostitis. (External view.)

deeper-seated inflammation. In cases of chronic inflammation of bone, accompanied by deep-seated and wearing pain, an opening made with a trephine, for the evacuation of pus, has proved beneficial, even though no pus was found.¹

Whether the sclerosis, or induration, which is the final result of chronic inflammation, be amenable to any remedial measures is doubtful, since it usually gives the patient little inconvenience, and therefore is not made the subject of treatment. Thickening over the bone is often left after osteitis, and is often dispersed by the ordinary measures, such as friction and pressure; but the seat of this thickening is very generally in the soft parts around the bone, and not beneath the periosteum.

Ostitis deformans.—A very curious condition, obviously the result of chronic inflammation, has been described by Sir J. Paget² under the name of 'ostitis

¹ See a case reported by Sir B. Brodie, in his *Lectures on Pathology and Surgery*, p. 410. On the good effects of a free incision of inflamed periosteum, when milder measures fail, see Sir P. Cramp on 'On Periostitis,' *Dublin Hospital Reports*, vol. i. p. 331.

² *Med. Chir. Trans.* vol. lx.

deformans.' Five cases are given which occurred under his own observation, and a few references to others more or less similar recorded by other authors. The disease occurs without known cause, but resembles chronic rheumatism in the pain which accompanies it. It is marked by a gradual enlargement of the bones affected; so that the head increases gradually in circumference, or the limbs in length, and at the same time the bones yield to pressure, causing curvature of the legs or arms, shortening and fixation of the spine, and change of shape of the thorax or pelvis. It does not seem that the disease in itself shortens life,¹ or that it is necessarily associated with any constitutional cachexia. Three out of Sir J. Paget's five patients died of cancer; but, as far as appears, this was only an accident. No treatment has hitherto had any effect. Sir J. Paget's paper contains illustrations both of the general features of the disease and of the rough and microscopic anatomy of the bones involved.

I ought here also to mention the curious cases which have been recorded by Virchow under the name of *Leontiasis ossea*, and which will be found referred to in Sir J. Paget's paper—a disease commencing in early life, and affecting the cranial and facial bones, causing a great increase in their bulk, so that they become 'hugely thickened, porous, or reticulate:' the cavity of the skull and the various cavities of the face are gradually encroached on by the enlarging bones, and so death is slowly produced. In connection with these may also be noticed the singular instance of periosteal formations on the skull, facial bones, hyoid bone, and fibula, recorded by Mr. De Morgan for Mr. Bickersteth, '*Pathological Transactions*,' vol. xvii. Mr. Bickersteth's patient died of exhaustion, apparently the result of encroachment on the cavities of the face. In none of these cases has any explanation been given of the origin of the disease, nor do they seem to be connected with syphilis or any other cachexia. Stromeyer alludes² to a case of gout in which nearly all the bones of one side of the body were hypertrophied; but no opportunity for post-mortem examination occurred.

Diffuse periostitis.—Inflammation of the bony tissue itself is rarely acute, and when it does occur in the acute form passes rapidly into necrosis, under which head it will be presently spoken of; but acute inflammation between the bone and periosteum, *diffuse periostitis*, is a disease of rather frequent occurrence. It is seen commonly enough in persons about the age of puberty; more frequently in boys than in girls; usually as the result of some injury, and almost always in one of the long bones. It is so destructive in its effects, so rapid in its course, and is so often overlooked or mistaken at first, that we have unfortunately numerous opportunities of verifying its existence after the time for treatment has passed away; yet to early and vigorous treatment it is tolerably amenable, at least as amenable as so acute a disease can be expected to be.

The pathology of the disease appears to consist in the partial separation of the periosteum from the bone, by effusion on the surface of the latter of lymph, or other products,³ soon giving place to a copious formation of pus, which spreads along the whole bone, and dissects away the periosteum from it, often from one end of the

¹ In one of the cases the movements of the thorax were so obstructed that the patient died of asphyxia.

² *Handb. d. Chir.* i. 442.

³ The disease does not commence by the formation of abscess; often when the swelling and inflammation are considerable, no pus will be found. Of this fact the following is an instance. A lad was suffering from what was supposed to be diffuse cellular inflammation around the ankle after a slight injury. As it was suspected that the inflammation was really subperiosteal, an incision was made down to the tibia. No pus followed. Two days afterwards the boy presented obvious symptoms of confined matter, and now by breaking up the adhesions of the wound a copious evacuation of pus was obtained, and the surface of the bone was felt exposed. A few days later, swelling and tenderness were found over a higher part of the tibia. Thinking that on the former occasion I might not have divided the periosteum freely enough, I now took care to press the edge of the knife firmly against the bone for some distance. Matters went on exactly as in the former wound. No pus was found at the time, but on breaking down adhesions, two days later, with a probe, the pus was discharged, and the bone was felt exposed.

bone to the other. If examined at an early period of the disease, the periosteum does not (at least it very often does not) display any distinct signs of inflammation, either in change of colour or of thickness; nor is the surface of the bone visibly inflamed. On the contrary, it usually looks white, and inclined to gangrene, a consummation which rapidly impends over such cases. Sometimes, however, the surface of the bone may be found slightly worm-eaten, and, on squeezing it, its superficial layers are found more readily separable from the deeper tissue than in health; large drops of blood can in such instances be pressed out of the vessels which pass into the bone from the periosteum. A little later, and necrosis is unmistakably declared, and the whole diaphysis usually perishes, leaving the articular ends unaffected, and therefore not involving the neighbouring joint.

The joint, however, does not always escape. A girl aged fifteen was admitted into hospital four days after an injury, with great swelling of the forearm, evidently depending on the formation of matter. A grating sensation, perceived on rotating the hand, together with the history of the accident, led to the belief that fracture had occurred. She died of pyæmia; and then it was discovered that a periosteal abscess, extending from the shaft of the radius into the wrist-joint, had so eroded the articular cartilages as to occasion the sensation of crepitus.

The course of the disease is usually as follows: it commences in the great majority of cases with an injury of more or less severity, occurring to a person generally of the strumous constitution, at any rate a weakly person; the symptoms which immediately follow the injury are usually slight, so that even the occurrence of the accident is perhaps nearly forgotten; then, after a varying lapse of time, probably four or five days, symptoms occur which are almost invariably attributed at first to diffuse cellular inflammation, or to acute rheumatism, viz. rigors, pain in the part, and an œdematous angry swelling. At the outset the diagnosis is not easy; indeed, before suppuration has occurred, perhaps no certain diagnosis can be made. However, as respects diffuse cellular inflammation, the age of the patient, the comparative remoteness of the cause, and the previous immunity of the superficial parts, will lead to a suspicion of the nature of the case, which will be strengthened when the inflammation is seen to be limited to the section of the member first affected, instead of passing the joint, and spreading up the limb, as an erysipelatous affection would in all likelihood do, and will be converted into certainty by the discovery of deep-seated matter, either by fluctuation or on puncture. Fluctuation cannot always be detected, since the tension of the membranes which bind down the pus, and the tenderness of the superficial parts, combine to oppose its discovery. Exploratory punctures, however, should never be neglected. If the disease be merely superficial, they can do no harm; and it is of vital importance to discover early, and give instant exit to, the pus before it has dissected off large portions of the periosteum, and involved the death of a great part of the bone. The diagnosis between a case of this sort and one of acute rheumatism will depend upon the nature and history of the disease, and on the presence or absence of constitutional symptoms of rheumatism, or rheumatic affections of remote parts. At the outset of the case the diagnosis may not be very confident; but the main point to recollect is, that any periosteal affection, if acute, is liable to run early into suppuration, and that in such cases, whatever view may be taken of the origin of the disease, whether it is to be considered rheumatic or otherwise, the local treatment is far more important than the constitutional. What Sir P. Cramp-ton says of the acute periosteal whitlow applies with much greater force to acute periosteal affections of the larger bones: 'There are few diseases where art can do so much and nature so little.'

If the disease be allowed to go on unchecked, the whole circumference of the limb will become greatly swollen and œdematous, usually with that tense glistening aspect which tells of subjacent suppuration. The patient mostly complains of great pain, especially acute at night; he loses appetite and flesh rapidly. Pyæmia is very liable to occur, and many of these patients die of it. A few die exhausted by the violence of the action, and by the profuse suppuration. If the patient survive, and the abscess do not obtain a free and depending opening by timely incisions, it will

burrow among the muscles, and ultimately numerous openings will form, exposing necrosed bone. The dead bone appears to separate much sooner than in other forms of necrosis, and the repair to be proportionately active. Thus, in an adult, almost the entire length of the shaft of the ulna was thrown off and removed three months after the injury which led to the complaint; and, even at that date, the repair appeared to be far advanced. In less acute cases, where only a portion of the surface of a bone is involved, the disease pursues the ordinary course of necrosis.

The subjects of this affection are almost always young persons,¹ in whom the strumous diathesis is well pronounced; but it occurs more rarely in healthy subjects about the age of puberty, or even earlier; and some cases are observed (as the one to which allusion has just been made) in adults of impaired constitution and dissipated habits.

The bone affected is, in the great majority of cases, the femur or tibia; and it is no doubt in consequence of the great size of these bones, and the severe effects which always attend ~~from~~ a large abscess situated below the fascia, that the disease is so fatal. But reference has already been made to two cases in which the bones of the forearm were attacked; and any of the long bones may be the seat of the disease, and not unfrequently is so. The flat and irregular bones are more rarely affected; but Sir P. Crampton's case² is well known, in which an acute abscess formed beneath the periosteum of the bones of the nose and cranium on both sides. A well-marked instance of acute periosteal abscess of the sternum is described in the '*Path. Soc. Trans.*' vol. xv. p. 181, and another less clearly described, but probably of the same nature, in vol. iv. p. 61 of the same series.

The treatment of acute periosteal abscess is a matter of the gravest importance, as it is only by vigorous measures that so rapid and dangerous an affection can be relieved. Among these measures, the first and most important is to make timely and sufficient incisions into the swelling. If doubt exists as to the nature of the swelling, or as to the situation of the pus, they will be settled by the grooved needle; but even if no pus be found, it is better in any case of acute periosteal inflammation, where the pain is great, to make an incision down to the bone in the part to which such pain is referred. In children, it will be advisable to administer an anæsthetic before commencing the examination when the affection is deep-seated.

Periostitis sometimes occurs in a sub-acute form, marked by rapid swelling around the bone, and by a certain amount of aching pain, but without the severe constitutional symptoms which accompany the graver disease. Incisions should not be made in these cases, unless the surgeon is sure that matter has already formed. The free application of leeches and local warmth will often obviate suppuration; and many surgeons have much confidence in iodide of potassium in full doses, as a remedy in this sub-acute form of the disease.

During the acute stage of a periosteal abscess, free exit having been obtained for the matter, the patient must be treated on general principles; no special internal treatment is necessary for the affection of the bone. The indications are, to allay pain, to support the strength, and to avoid, if possible, the constitutional affection which leads to pyæmia. The last is the most important of all; patients seldom die of the 'surgical fever,' so called, which is usually present; they seldom die of the exhaustion of the discharge; but they die by pyæmia in a large percentage of the cases. Free and early incisions give the patient the best chance of escaping this fatal complication. No fear need be entertained of decomposition of the pus from the admission of air. In fact, pus which is confined over a bone in an acute inflammatory disease, will probably be already sufficiently putrid. After the opening, the

¹ Chassaignac says, that out of eleven cases, only one had passed the seventeenth year, and was below twenty-one; and one was only eleven months old. In the '*Path. Soc. Trans.*' vol. vi. p. 284, a well-marked instance is recorded at the age of eleven days. A circumstance which seems to testify to the effect of a constitutional predisposition is mentioned by Chassaignac, viz. that in some cases several acute periosteal abscesses have been present in the same subject (*Mém. de la Soc. de Chir.* vol. iv. pp. 286-7).

² *Dublin Hospital Reports*, loc. cit.

cavity of the abscess should be frequently syringed out with antiseptic solutions. The openings should at first be made in as depending a position as possible, and they should be so free as to preclude all risk of their closing again. Free stimulation is generally, if not always, necessary. The patient will, perhaps, be unable at first to take solid nourishment, since these affections are generally attended with severe fever; but as soon as the evacuation of the matter has removed some part of the irritation, his appetite will probably return.

If the patient has survived the acute stage of the disease, the abscess may long remain in a chronic condition, exposing the bone. In the more favourable cases, the outer shell only of the latter has perished; while in the most severe, the entire shaft, separated from the epiphyses, may come away in a mass; or even the epiphyses themselves may share in the destruction, though that is not often the case. The treatment of these sequelæ of diffuse periostitis will be spoken of in the section on Necrosis, where also will be found discussed the subject of sub-periosteal resection for acute disease.

Epiphysitis.—A very interesting and formidable variety of acute inflammation is that which affects the epiphyses in early life. This is closely connected with acute periostitis, and with osteo-myelitis; but as it leads to degeneration of the joints, it has been thought better to treat it among DISEASES OF THE JOINTS.

Osteo-myelitis.—Diffuse inflammation, and suppuration, in the cancellous tissue, an affection to which French pathologists have given the name of 'osteomyelitis,' is more frequently recognised in post-mortem examinations than at the bedside of the patient. This affection, when it is most acute and extensive, is closely allied to pyæmia, and is frequently followed by that mode of death. It bears the same relation to the medullary tissue as the complaint just spoken of does to the periosteum; but the difference in character between the periosteum and the medullary tissue, the latter being so much more rich in vessels, especially in large patulous venous channels, gives to osteomyelitis a gravity even beyond that of diffuse periostitis. It is well known how often diffuse suppuration is found in the diploe of the cranium after scalp-wounds, and how the 'puffy tumour of Pott' is frequently only the sign of such suppuration; and further, in what a large percentage of such cases evident pyæmia is found. It is probable that in all these cases the external table of the bone has been wounded, and the diploë thus exposed; in fact, the only known cause of osteomyelitis is a wound which exposes the cancellous interior,¹ or an injury to the interior of the bone, perhaps unaccompanied by external wound, as in fracture or severe contusion.² It is a frequent cause of death after amputations and other surgical operations in which bone is divided. Lately, in Italy attention has been called to the connection which has been observed to exist between inflammation of the medulla of the bones, and the disease of the spleen and other blood-glands, so often resulting from the malarious fevers there prevalent, and the observation is an interesting one, especially in view of the function which physiologists now agree to give to the medulla of the bones in the formation of the blood-corpuscles.³

When a bone is examined in which osteomyelitis has run an acute course, the cancelli are found loaded with pus, and the medullary tissue usually injected and often sprinkled with ecchymoses; the periosteum also is often in the course of separation from the bone; but the bony tissue itself does not necessarily show any appreciable change. When it does the changes are such as are described on p. 276. In the larger bones the disease usually terminates fatally at this stage; but should the patient survive, the pus may penetrate into the neighbouring parts, most probably into the nearest joint, or central necrosis may result.

¹ Unless the infection of constitutional syphilis should be added. See *infra*, on 'Syphilis in Bone.'

² Mr. Macnamara has also met with cases of acute osteomyelitis attributed to exposure to cold.

³ See Dr. Tassi's pamphlet, *Studi di Anatomia patologica e Clinica sulle Malattie delle Ossa*. Rome, 1877.

Specimens to show either of these terminations are not wanting in our pathological collections. Thus, in the Museum of St. Bartholomew's Hospital there is a beautiful specimen (i. 207) of inflamed and thickened medullary membrane of the humerus, which shows, as a consequence of the inflammation, a portion of cancellous tissue exfoliated and lying loose in the medullary canal. A long fistula leads through the tube of the bone into the elbow-joint. The same Museum possesses another specimen (i. 195), in which acute diffused suppuration, spreading through the tissue of many of the long bones, has caused abscess in the knees and ankles on both sides.

The symptoms of this grave affection are exceedingly obscure: it, like other extensive and acute affections of bones, is often accompanied by diffuse inflammation of the soft parts, which then masks the deeper affection. Rigors and general fever always mark the onset of acute osteo-myelitis, but the only known special symptom of the disease in the bone is the separation or recession of the periosteum from it, accompanying diffused pain in the bone, and not caused by effusion on the external surface of the latter. After amputations, a prominent fungous mass is often seen projecting from the end of the bone, and proves the existence of a certain extent of inflammation of the medullary tissue; but this need not necessarily have affected the bone so extensively as to deserve the name of osteo-myelitis; in fact, that affection is seldom recognised before death.¹

To obviate the formidable dangers, and the extensive disintegration of parts connected with osteo-myelitis, it is justifiable in any case where pain in the bone, accompanied with the ordinary symptoms of acute suppuration (rigors, fever, &c.), but without signs of external or periosteal mischief, induces a reasonable suspicion of this affection, to expose the surface of the bone by a free incision. Should the periosteum be found separated, or even separating, from the bone, the diagnosis of diffused suppuration in the cancelli will be rendered highly probable. When this separation of the periosteum has proceeded to any great extent, amputation of the member, or excision of the diseased bone, is certainly indicated. It should be remembered that the disease is a rapid one, the fatal complications of internal phlebitis and pyæmia imminent; and therefore treatment, to be effectual, must be adopted early. Medicine, as might be expected, has little effect on the disease; but the fever which accompanies it should, of course, be treated on the ordinary principles. In deciding on the question of removing the diseased bone (an operation which would in ordinary cases be held to be contra-indicated if pyæmia had set in), it should not be forgotten how obscure the early symptoms of systemic affection are, so that it may be proper in doubtful cases to give the patient the benefit of the doubt, and attempt to relieve him from the source of irritation.

How far it is possible, in practice, to separate acute periostitis from acute osteo-myelitis is a question on which surgeons differ widely. Many French and German pathologists seem hardly to admit the existence of the disease which I have described above as diffuse periostitis, apart from osteo-myelitis, of which, indeed, they consider it as merely a complication. Some, without going so far as this, yet say that the whole thickness of the shaft of a bone never perishes unless the medullary tissue is involved. I have, however, seen convincing instances to the contrary; and I am confident that cases of acute periostitis do occur in which the whole thickness of the shaft (and sometimes the entire shaft) perishes, without any implication of the medullary membrane; though I allow that, in most cases of diffuse periostitis implicating the whole thickness of a bone, the medullary tissue is more or less involved.

In chronic osteo-myelitis the removal of the limb is frequently successful in affording the patient relief from an abiding source of irritation, which will at length

¹ If after an amputation acute osteo-myelitis be suspected, the surgeon can establish his diagnosis by putting the patient under chloroform, and ascertaining by means of the probe that the whole medullary tissue is broken up for a considerable distance, as well as the small portion which is projecting out of the wound. See Payrer, in *Indian Annals of Med. Science*, Oct. 1865. 'The symptoms of acute osteo-myelitis are pain in the part, œdema, and swelling extending down the limb; general fever, with quick pulse, and increased temperature, and more especially the recession of the soft parts, including the periosteum, from the bone, which is then left denuded at the bottom of the wound.'—*St. George's Hospital Reports*, vol. i. p. 156.

otherwise prove fatal; but when this affection is limited to a portion only of the bone, the expectant treatment is indicated, and the patient may recover after the extraction of a sequestrum.¹

Chronic abscess.—Limited suppuration, or abscess in the cancellous tissue, is an affection which is fortunately far more easily recognised, and far more under the control of surgery, than osteo-myelitis. It hardly needs to be said that this condition of bone was first discovered and described by Sir B. Brodie.² The symptoms are not always very clear, but a careful study of the case seldom fails to establish the correct diagnosis. The seat of the disease is almost always the articular extremity of the bones which form one of the great joints—knee, ankle, or elbow. The tibia is more frequently affected than any other bone, and usually at its upper end. Chronic abscess may, however, occur in any situation.³ The abscess is almost always situated on the superficial side of the bone, and is probably occasioned, in most cases, by external violence, or other causes, acting on that surface; but the history is often obscure, in consequence of the chronic nature and insidious progress of the malady.

The symptoms are, a dull aching pain in the part, often worse at night than during the day, liable also to other remissions and exacerbations, and increased by exercise or pressure. In most cases the bone is especially tender at one particular spot, where the abscess has advanced nearest to the surface, and there is slight tumefaction of the soft parts over it. Sometimes, but not always, a little enlargement of the bone itself may be made out. There is perhaps nothing very characteristic in these symptoms taken separately, or on a first examination; but the persistence of the whole assemblage of them for a considerable period of time, and in spite of judicious treatment, directed to subdue an inflamed condition of the bone, will be reasonable ground for the diagnosis of chronic abscess, and more especially if the neighbouring joint be unaffected. The localised, and very circumscribed, tenderness is perhaps, when well marked, the most unmistakable symptom.

The condition of the diseased bone testifies very clearly to the nature of the morbid process, so that few museums are without some of these preparations. The following is Sir B. Brodie's description of the first preparation which he dissected: ⁴ 'The lower end of the tibia is enlarged, and the surface presents marks of great vascularity. The bone in the preparation is divided longitudinally, and just above the articulating surface there is a cavity as large as a small chestnut. This cavity was filled with dark-coloured pus. The inner surface of it is smooth. The bone immediately surrounding it is harder than natural.'

If the case be allowed to proceed beyond this stage, serious and frequently fatal mischief may ensue from the extension of the abscess into the neighbouring joint. Before this event occurs, however, the patient may be much inconvenienced by repeated attacks of swelling and pain in the joint when he attempts to use the limb, the effects of slight synovial inflammation set up by the neighbouring abscess. Rest and cold applications will generally remove these symptoms, but only to recur as soon as the patient again attempts to move about. On the cure of the abscess they will immediately and permanently disappear. When the abscess has burst into the joint, the affection of the bone becomes merged in the more serious injury to the articulation.

Treatment.—In all cases, as soon as the diagnosis has been so far settled as to satisfy the surgeon that operative interference is justifiable, he ought to explain the

¹ I would refer, on the subject of chronic and acute osteo-myelitis, to the well-known paper by M. J. Roux, read before the *Académie Imp. de Méd.*, and to the criticisms of M. Legouest, M. Larrey, and others on it, which are to be found in the Society's *Bulletin* for 1850-50, vol. xxv.; to a paper by Mr. Longmore, in *Med.-Chir. Trans.* vol. xlviii.; and to one by myself, in *St. George's Hospital Reports*, vol. i., quoted above.

² *Lectures on Pathology and Surgery*, ed. 1846, p. 395.

³ In the Museum of St. Thomas's Hospital there are examples in the body of a rib, in the clavicle, and sternum. Series U., Nos. 84, 84², 85.

⁴ *Op. cit.* p. 307. The original preparation is in the Museum of St. George's Hospital, series ii. 30.

nature of the case to the patient, and endeavour to obtain his consent to the simple operation which will at once establish the diagnosis and cure the disease; or the diagnosis may be confirmed by perforating the bone in the suspected spot with the hand-drill, as recommended by Mr. Macnamara.¹ The suspected part of the bone should be well exposed by a crucial incision. The bone should then be perforated to a considerable depth with a small trephine, which should not have a shoulder. If one spot on the surface of the bone appears softer than another, this should be selected for the centre of the opening. Very often pus will be seen welling up in the groove, as soon as the trephine has penetrated the compact wall of the bone. The instrument may then be withdrawn, and on the circle of bone being raised with an elevator, the pus will be evacuated. The cavity exposed is lined with a thick 'pyogenic' membrane, and its surface is very sensitive. The pus is only in small quantity (generally about a tea-spoonful); but its evacuation suffices at once to relieve the patient of his wearing pain, and he is soon restored to perfect health, the cavity being filled up with a fibrous material, by which in all probability the excised piece of bone is ultimately reproduced.

FIG. 47.—Unsuccessful Trephining in chronic Abscess of Bone. (From a preparation in St. George's Hospital Museum. Series ii No. 31.)

a, the point where the trephine has been applied about half an inch from the abscess, *b* the wall of the bone, thickened by inflammation, *c*, the cavity of the abscess, *d*, the pyogenic membrane.

Two things may interfere with the complete and immediate success of this operation—the diagnosis may have been correct, but the place selected for trephining may have been not quite the right one; or the diagnosis may have been wrong, and the symptoms have depended merely on chronic osteitis or chronic osteo-myelitis. In the latter case, as may be seen by Sir B. Brodie's patient above referred to (pt. 281, note), the operation will often do good, will relieve the pain of the inflammation, and perhaps prove the starting-point of a healthier action. It is well, however, remembering that this mistake has been committed by the best surgeons, to prepare the patient for it, so that he may not be too much disappointed if the surgeon shall afterwards have to confess that no abscess was found. If, however, the trephine do not come down upon an abscess, it should not be forgotten that this may depend on the opening having been made on one side of the abscess, which may be lying close to the trephine-hole, but separated from it by a thin bony septum. This is illustrated by the accompanying drawing from a preparation in the Museum of St. George's Hospital. It is advisable, therefore, when the pus has been missed, before giving up the operation, to pierce the walls of the trephine-hole in several directions with a sharp-pointed instrument, in order to remove the bone freely with a chisel if a drop of pus follow any of these punctures.

¹ *Diseases of Bones and Joints*, p. 31.

Caries.—The word caries will be used in the sequel as equivalent to the term 'ulceration of bone.' The term is now employed in very various senses, especially by the German surgeons; and so difficult has it thence become to follow its exact meaning in different works that Billroth proposes to abandon it altogether. This, however, would involve a change in accepted surgical nomenclature, and a consequent confusion for which we should obtain no compensation. I can see no difficulty or ambiguity in using the word 'caries' as I have here suggested, except perhaps in cases of inflammation of bone attended with absorption, but without suppuration or open sore—cases such as are spoken of on p. 293. To these I should apply the term 'inflammatory absorption,' or 'ulcerative absorption;' and it is to these that the term 'caries sicca' of the German surgeons appears most applicable; but such cases are so rare in practice that it matters little what name we give them. The simplest nomenclature seems to me to be that which calls cases of inflammation without suppuration 'ostitis,' and cases of ulceration 'caries,' adding to the latter

FIG. 48.—Strumous (or so-called 'carious') Ulceration of Bone. (Museum of Royal College of Surgeons, No. 625.)

name any qualifying designation, such as 'simple,' 'traumatic,' 'strumous,' or 'syphilitic.'

Superficial ulceration is distinguished by the following characters. The periosteum is loosened from the surface, and, if the disease is advanced, will be found much thickened, and converted into a villous mass of a pink colour, resembling a layer of granulations. This substance adheres very loosely to the surface of the bone, and when lifted up from it, it is found to fit into depressions, which seem to have been hollowed out of the bone by the agency of the granulations. The bone at a very slight depth underneath is found, in most cases of healthy inflammation, of the ordinary consistence of cancellous tissue, which it resembles in structure even in those parts which ought to be compact. In strumous caries, on the contrary, the osseous structure will be found softened and otherwise altered, as will be described when treating of struma in bone; and it is to this combination of strumous inflammation of the body of a bone with ulceration of its surface, that the old descriptions of caries appear to be intended to apply. The ulcerated surface in healthy inflammation is superficially excavated, much softened, and easily broken

down by the pressure of a probe. The interior of carious bone is softened by inflammation, its cancelli enlarged, and filled with the products of the softening and disintegration which have been going on around them. These products, as has been noticed above, are principally oil-globules, blood, and other débris of the soft tissues, and granular inorganic materials, having the same chemical composition as the salts of the bone. The soft tissues almost always take part in the morbid actions which lead to caries, and abscesses are formed which burst externally, and leave sinuses communicating more or less directly with the softened bone, and through which some part of its exposed surface can generally be felt with the probe. Abscesses, however, frequently form in the neighbourhood of inflamed bones without any actual communication with them. This is, perhaps, more peculiarly the case in childhood, and near the joints.

Symptoms.—The symptoms of caries are merely those of inflammation *plus* an abscess exposing softened bone; hence all that has been said about the frequent obscurity of the early stages of osteitis will apply to caries, and with greater force, inasmuch as these ulcerative actions are more prone to occur in the course of low inflammations. Constant pain, then, in the neighbourhood of a bone, with swelling and more or less loss of the function of the part, followed by abscess which will not heal, indicate usually that the abscess proceeds from ulceration of a bone; and this presumption is much strengthened if the pus have a putrefied, offensive odour, and a prominent mass of granulations project from the sinus; and it is converted into certainty if fragments of bone can be found in the discharge, or if the communication with the bone is sufficiently direct to allow of its being struck with a probe. When carious bone is touched by the probe, it is not usually found particularly sensitive, perhaps is not sensitive at all; it bleeds readily; its surface is irregular, and may generally be felt to be soft. When the opening is sinuous and the bone cannot therefore be struck, the diagnosis can of course only be inferential, and founded mainly on the persistence of the symptoms. Chemical analysis of the pus may also sometimes assist the diagnosis, since the pus from diseased bone contains more phosphate of lime than that from soft parts.¹ Sometimes the patient's sensations afford valuable evidence, more particularly in caries from healthy inflammation, where striking lightly over the carious part often causes the same kind of sharp pain as is felt when a carious tooth is struck. (See also footnote ², p. 279).

Caries is generally accompanied by more or less of plastic or organisable effusion in the bone in the neighbourhood of the ulcerated spot, leading to condensation of the deeper parts of the bone, and to periosteal deposit of bone on the surface. This, however, is the case only in those instances where the process partakes of the healthy or sthenic character. In those low inflammations which are usually called strumous, whether connected with obvious deposit of tubercle or not, such thickening or periosteal deposit is often absent; but the bone is softened throughout all the affected portion, the disintegration becoming less and less perceptible at a distance from the part where the loss of substance exists. The deposit around ulcerated bone frequently leads to ankylosis of the less movable joints; an occurrence which is extremely common in the tarsus.

In cases of superficial ulceration of bone, the agents for its removal are either the periosteum, when that membrane remains entire, or the granulations which spring from inflamed surrounding parts when the periosteum has been removed. Other cases, however, of ulceration are met with, in which the disease is more deeply seated, and commences in inflammation of the membrane lining the cancelli or medullary cavity, and where, therefore, the agents for the removal of the bone are to be sought in the vessels of this membrane. Such cases as these are very rare. I am able to refer to preparations showing the reality of the affection,² but I have no knowledge of the special symptoms which it presents, or the indications, if any, which it furnishes. It is evident that, shut up as the inflamed parts are in the interior of the bone, the products of inflammation can find no exit, and the disease

¹ Bransby Cooper, *Lectures on Surgery*; Barwell, *On Diseases of the Joints*, p. 238, 1861.

² St. Bartholomew's Hospital Museum, series i. No. 163.

must soon become merged in one involving¹ more extensive destruction, i.e.,^h in diffused suppuration or internal necrosis.

Ulceration in bone, like ulceration in soft parts, may terminate in cicatrisation^h, or the reproduction of an inferior kind of bone which is less vascular, and less smooth and well formed than the portion which it replaces. This fortunate termination becomes less probable, the deeper the disintegration of the bone extends, and the more profound is the constitutional cachexia with which it is associated. In extensive strumous caries it is hopeless.

The *treatment* of bone affected with this form of inflammation is a matter of great importance; since upon the success or failure of such treatment, the preservation of the bone, and with it sometimes of the limb, or even the life of the patient, may depend. Ulceration in bone does not differ materially from the same process in soft parts, except in the far greater length of time which it usually occupies. In the bone, as in soft parts, the powers of nature will in most cases suffice for cure, when cure is possible, if the parts be put in a suitable position, kept at rest, and preserved clean and free from the accumulation of the discharges. But often the patient cannot wait for the completion of this natural process, and calls upon the surgeon to deliver him from the chronic malady which has become insupportable. Or, sometimes his health gives way under the protracted discharge; or, after an interval of quiescence, the caries again makes progress, and threatens to involve neighbouring bones, and to impair the functions of the whole limb, if not arrested. This is more peculiarly the case in the tarsus, and other 'irregular' bones. In the ordinary treatment, then, of caries, no other local measures are required than to provide a free exit for the discharges, and to keep the exposed surface of bone clean. The appropriate constitutional treatment will complete all that art can do to promote recovery, and more active surgical interference is not only useless but hurtful, as it risks doing harm without a reasonable prospect of doing much good. Incisions, however, should not be spared to the utmost extent necessary to keep the discharge free, or perhaps even somewhat beyond this limit. In fact, in all the acuter cases of osteitis, much benefit appears to follow the mere division of the tense structures over the bone. When the surface can be felt exposed and carious, it is still more necessary to have a free discharge; since otherwise, the pus, being confined, may burrow beneath the periosteum, and extend the mischief to the neighbouring parts of the bone.¹ Mr. Lister and his scholars lay much stress on the employment of the antiseptic method in such cases. The bone being freely exposed, and, if necessary, perforated with the trephine, the wound is to be kept perfectly 'aseptic,' and will then heal gradually.

Often after this free exposure of the carious bone, the disease will gradually subside; but when this is not the case, the question occurs, whether it will be proper to attempt to remove the carious surface and expose a more healthy one, either by rasping or gouging the bone, or by the application of the actual cautery; or to modify the diseased action by injections, or by applications to the carious part.

In cases of superficial caries of bones which can be exposed without too much injury to the soft parts (of which the tibia and calcaneum are the most familiar examples), it may sometimes be advisable to rasp or gouge away the carious surface of the bone, and endeavour to arrest the further progress of the disease by the application of the actual cautery or strong nitric acid to the surface so exposed; or, if the disease be very superficial, the latter measures may be sufficient, without any preliminary removal of bone.

Mr. Pollock has employed the application to the carious surface of sulphuric acid, at first diluted with an equal bulk of water, and then more and more nearly pure, pencilled on the surface when exposed by turning away the soft parts. The first application dissolves a portion of the exposed bone, and chars and kills the rest of the surface; when this comes away, if more dead or diseased bone is exposed, it

¹ Some authors teach that pus exercises a solvent power upon the bony tissue itself. This doctrine appears unsupported by direct evidence; and it seems improbable that the bone can be so dissolved while it retains its vitality.

can be similarly treated until a healthy granulating surface is reached. In this way also superficial exfoliations of necrosed bone can be removed. I have witnessed the success of this plan in the hands of my colleague, and can speak also favourably of it from my personal experience.

Another plan, which is applicable also to the treatment of caries in more deeply-seated bones, has been proposed by Dr. Fitzpatrick.¹ He converts the sinuses leading down on to a diseased bone into a large funnel-shaped opening, by the repeated action of the Vienna paste (*potassa cum calce*), and having thus brought the diseased bone within reach, he pierces its tissue with a strong knife, trocar, or small trephine, and then freely cauterises the full extent of the perforation. The cauterisation is to be repeated till the whole extent of the disease seems to be removed, and the use of the limb is restored. Necrosis can, according to Dr. Fitzpatrick, be treated in the same way: 'the caustic being very freely used, destroying all foul undermined integument, and leaving large clean circular openings, more than an inch in diameter, and extending deeply down into the sequestrum, into contact with which the caustic in stick and powder is to be freely brought.' He recommends it also in simple inflammation (a recommendation in which I cannot say that I concur), but not in diffused suppuration. My personal experience of this treatment has been limited, and in one case which seemed peculiarly well suited for the treatment, and where the disease, which was seated in the ankle, was in a perfectly chronic state, the patient died of pyæmia.

These operations should, however, only be performed in cases of evident necessity. We have only too frequent instances of the dangers of all operations on bone, especially of such as involve the exposure of large surfaces of the cancellous tissue, as is generally the case in these gouging or rasping proceedings, which are extremely apt to be followed by diffused inflammation of the interior of the bone (*osteo-myelitis*) and by pyæmia. Still, if the disease be accompanied with much pain and loss of motion, and the wound show no tendency to heal, the patient is often compelled to have something done for his cure, as otherwise he would lose his means of livelihood; or the surgeon may think it right to interfere in order to arrest the progress of the disease into neighbouring organs. The decision of such questions as these must, of course, be left to individual judgment.

The application of the actual or potential cautery appears to be less dangerous than cutting operations, and is often successful in superficial caries. It seems less in use than might be expected, considering the many cases of caries limited to one, and that a superficial, bone of the tarsus and metatarsus, which are seen, especially in children. Here, however, and in all situations where a bone can be removed without prejudice to the function of the part, excision is so much more satisfactory when any large part of the bone is involved, that it is, perhaps, not wonderful that the less radical measures are not much in use.

M. Sédillot has proposed a more extensive use of the operation of scooping or gouging carious bone, as a substitute for excision or amputation.² His plan contemplates the removal, by the gouge, of the whole bone except a shell of the outer healthy parts, which is left to effect the restoration of the bone. With all due respect for the authority of M. Sédillot, it seems impossible to allow that such a proposal is either useful or safe. There are few cases of extensive and deep-seated caries in which the limits of the disease can be ascertained, and a partial operation is often worse than none at all. Besides, extensive exposure of the interior of a bone is a most hazardous proceeding, and only too often terminates in pyæmia. M. Sédillot, however, is said to have performed his operation thirteen times without any instance of such complication. The further consideration of this question will occupy a portion of the *essay on* EXCISIONS.

Ulceration in bone is not always of this chronic nature. Mr. Stanley has described³ some cases of 'phagedænic ulceration' of bone which seem to have been

¹ See *New Syd. Soc. Biennial Retrospect*, 1807-8, p. 250.

² *Lancet*, Dec. 10, 1859; Sédillot, *Sur l'Evidement des Os*.

³ *On Diseases of the Bones*, p. 65.

connected with the occurrence of rodent or canceroid ulcer in the soft parts; and in diseases more distinctly partaking of the nature of cancer the bones may be destroyed with great rapidity; but here the affection in the bones is only a part of the general disease, and its treatment must depend on the view which may be taken of the latter. Cases of rapidly spreading ulceration do, however, occur, in which the bone alone is affected.

Two remarkable instances have been put on record by Mr. Caesar Hawkins;² in one of which the disease was only part of a general strumous affection, but peculiar on account of its extreme rapidity and great extent. The other was a very remarkable instance of removal, by disease, of great part of the skull-cap, and protrusion of the brain through the opening so left; but without the formation of pus. An abscess was found in the brain, but this was connected with violence done to the protruded portion of that organ, and not with the disease in the bones. No distinct proof of the presence of any constitutional cachexia was obtained, nor was the exciting cause of the complaint apparent. Its inflammatory nature was testified by distinct marks both of inflammatory thickening and of inflammatory erosion on the bone in the neighbourhood. Therefore the old definition of ulceration as 'absorption from inflammation' would strictly apply to this extraordinary case; but it is rarely indeed that so large a portion of bone is removed without the formation of abscess, especially when compact tissue is involved. Norris, however, in his 'Contributions to Practical Surgery,' p. 55, has recorded a very singular case in which, after a simple fracture of the arm, reproduced by a second accident during the uniting process, the whole humerus gradually became absorbed, without any formation of matter. The patient survived the injury thirty-four years, and the fact of the total disappearance of the whole shaft of the bone, leaving only a small piece at either extremity, was verified by dissection. A somewhat similar case occurred in Mr. Wheelhouse's practice.³

Necrosis, or the death of some considerable portion of a bone, occurs as the consequence of any cause which sufficiently impedes the circulation in the neighbourhood. This is precisely analogous to what takes place in the gangrene of soft parts; and as in gangrene the non-vascular parts are most easily affected, and then those which, though vascular, are furthest from the centre of the circulation, and in which the vessels are fewest and smallest, so the frequent occurrence of necrosis of bone is, no doubt, due to the comparatively small quantity of blood which circulates in that tissue, as well as to the inextensible nature of the osseous substance itself, in consequence of which any extravasation or product of inflammation causes pressure directly upon the blood-vessels, or narrowing of the channels for the conveyance of the nutritive plasma.

The same causes which produce gangrene in soft parts will occasion the death of a bone; and among them inflammation holds a high place, less on account of its direct effect, *i.e.* its tendency to produce the death of the part inflamed, than of its indirect consequences, whereby the circulation around the inflamed part is obstructed, and so necrosis of the neighbouring parts is induced. Hence in the course of an extensive caries the circulation of some considerable portion of the bone is apt to be destroyed, and then a necrosed or loose piece is found in the middle of the ulcerated part.⁴

Another very frequent, if it be not the most common, cause of superficial necrosis is the denudation or separation of the periosteum, which occurs as a consequence either of direct injury or of effusion between it and the bone. It is true that large separations, and even extensive destruction of the periosteum, may occur without the death of any portion of the bone, and this is indeed common in the bones of the head and face; but the peculiar circulation in the former, and the great vascularity of all parts in the latter region, sufficiently explain this fact. In other parts, it is the more general rule that when the periosteum is destroyed or separated over any considerable

¹ See vol. i. p. 154.

² *Med.-Chir. Trans.* vol. xxxix. p. 285.

³ In the *Wiener Med. Wochens.*, Dec. 7, 1878, Nedossil relates a case in Billroth's practice in which almost the entire radius was absorbed in a case of constitutional syphilis with much pain and swelling, but without suppuration. In a note to this paper Billroth refers to other instances of absorption without suppuration.

⁴ This combination of caries and necrosis was called by the old writers 'dry caries' or 'hard caries.' It is a different condition from that which modern German pathologists intend by 'caries sicca.' That term appears to me to be applied, in a very loose and unintelligible way, to several varieties of osteitis. See p. 289.

portion of a bone, the superficial layers of the latter will perish. This is one reason, among many, why it is important to adjust the soft parts over a bone denuded by violence, in order that they may rapidly adhere to it, and that so fresh vessels may connect the periosteum to the bone before the latter has undergone an irremediable change.

Violence, acting directly upon the bone, is another very frequent cause of necrosis, as is frequently seen in compound fracture, where both the periosteum and the medullary tissue are much damaged, and the bone dies without any proof of previous inflammation having existed.

The action of cold is often exhibited on the bones as on the soft parts, and they frequently suffer in frost-bite (vol. i. p. 129). In deep burns the bones are also occasionally charred, and they are frequently involved in gangrene of the superficial tissues, from whatever cause it arises. Certain caustic applications are well known as frequent causes of necrosis, of which the superficial exfoliation produced on the surface of the jaw for the cure of epulis is a familiar example. To this category belongs also the necrosis of the jaw which is produced by exposure to the fumes of phosphorus.¹ The various constitutional cachexiæ, especially syphilis and struma, are frequent causes of necrosis; but here the affection of the bones is only a variety of the inflammatory process.

The abuse, and even occasionally the moderate use, of mercury is another cause of necrosis. It is quite true that many of the preparations and cases entitled 'necrosis from the abuse of mercury' may be explained as having been cases of syphilitic necrosis, in which mercury had merely failed to arrest the disease, and had had nothing to do with causing it; but there are too many instances on record of the occurrence of necrosis of the jaw, during the administration of mercury for some disease which has no influence upon the bones, to admit of a doubt that the affection was directly induced by the so-called remedy. Thus, in the Museum of Guy's Hospital (No. 1,091) is a sequestrum consisting of two-thirds of the alveolar process of the lower jaw, which is said to be 'necrosis induced by the use of mercury for ovarian dropsy.' In the Museum of St. Bartholomew's Hospital is a preparation, in which necrosis of the jaw is attributed to the administration of a few grains of mercury during a fever; but in some fevers necrosis has been frequently observed as a consequence of mere lowering, as it would seem, of the vital powers, or some morbid condition of the blood, without any mercurial cachexia.²

It would be idle to attempt an enumeration of all the causes which may lead to the death of bone. The above are the most common, and will be found sufficient for practice. The symptoms and treatment are identical in most of these forms. Some will require special notice hereafter.

When a portion of bone is to die,³ the first phenomenon is the cessation of circulation in it. This leaves it hard, white, and sonorous when struck. It does not bleed when exposed or cut into, and is insensible. Occasionally, when the dead bone is exposed to the air, and acted on by the presence of putrid pus, its colour becomes nearly or quite black; large surfaces of hard, black, necrosed bone are sometimes left exposed by the sloughing of the skin over the tibia. The dead bone at first retains its connection to the bone around, as well as to the periosteum, or whatever part of the nutrient membrane may belong to it; but the presence of a dead part is never long tolerated by the living tissues, and accordingly the processes which are to eliminate it soon become perceptible on both these structures. The periosteum, or medullary membrane, as the case may be, separates from the dead bone and becomes inflamed, a quantity of ossific deposit (more or less, according to various circumstances) is poured out between it and the dead bone, and this deposit soon becomes

¹ This affection will be found treated of in the essay on SURGICAL DISEASES OF THE TEETH AND GUMS.

² See, in the Museum of St. George's Hospital, series ii. Nos. 91, 95, preparations in which both the jaw and the clavicle became necrosed in the same patient during the course of the fever.

³ This description refers to the process as it occurs in bone previously healthy.

converted into new bone, forming a sheath over the dead portion, by which the latter is enclosed, or *invaginated*, as the technical term is. The dead part is now called a *sequestrum*, a name only properly applied to it when loose and invaginated, though often incorrectly used of any piece of dead bone. While this sheath is being formed from the membrane coating the dead bone, changes are going on in the living bone to which it was attached. When the latter has been previously diseased (i.e. when the necrosis has been of inflammatory origin), the inflammatory deposit which surrounds the sequestrum softens, pus is formed, and a groove of ulceration is produced at the expense of the circle of inflamed bone which forms the margin of the sequestrum. If the surrounding bone have been previously healthy, the sequestrum acts as an irritant upon it, setting up, first inflammation and thickening to a variable distance, and then ulceration. Thus a groove is traced around the sequestrum; and the formation of this groove is accompanied by suppuration, as has been described above (see p. 278). The pus formed in the neighbourhood of the dead parts makes its way to the nearest surface, and in so doing interrupts the formation of the

FIG. 40.—From a preparation (No. 3174) of Necrosis of the Tibia, in the Museum of the Royal College of Surgeons. To show the various points connected with necrosis of a portion of the shaft of a long bone—the sequestrum—its invaginating sheath, formed in a great measure by periosteal deposit, and terminating on the healthy surface of the bone, at some distance from the seat of disease, the openings, or cloacæ, through which the sequestrum is exposed, and (in this instance) the implication of the neighbouring joint from the extension of these cloacæ into it.

periosteal sheath, leaving sinuses, or *cloacæ*, passing through this sheath from the sequestrum to the surface of the body, or sometimes into a neighbouring joint or serous cavity. The presence of such sinuses, leading through the shell of bone to hard, smooth, sonorous bone at the bottom of the cavity, is the distinguishing mark of necrosis. Most of these points are illustrated by the accompanying figure.

The formation of the groove between the dead and living bone is a very slow process in the bones of the limbs, requiring generally many months for its completion. It is impossible to lay down any rule as to the time at which a sequestrum may be expected to be found separated from the rest of the bone. In animals, as has been proved by experiments,¹ the process may be completed in a few days. In children it seems to go on sometimes with great rapidity, especially in the bones of the face. On the other hand, instances are not wanting in which half a lifetime may have elapsed, and the process still remain unfinished.

One of these has furnished a preparation in the Museum of St. Bartholomew's Hospital.² It is the section of the shaft of a femur, exhibiting in its interior a small fistulous cavity, with necrosis of a small portion of the inner layers of its wall. A groove extends to some

depth between the dead and the contiguous living bone. The limb was removed by amputation. The femur had been fractured thirty-five years previous to the amputation; the fracture was followed by abscess in the soft parts, and the formation of a fistulous passage leading to the interior of the bone, which passage remained open during the whole period from the fracture to the removal of the limb.

It may, however, be stated generally, that the more superficial the dead portion is, the more freely it is exposed, and the more violent the action of the cause has been, the more rapidly will it separate (see p. 284).

When the groove is completed, the dead bone is loose in the cavity so formed for it, and quite free from any vital connection to the body. The sequestrum, therefore, is now eliminated, and this may be regarded as the natural process of cure, since it prevents the extension of the necrosis further into the bone; but as the sequestrum is still lodged in its cavity in the interior of the bone, it thus becomes an abiding source of life-long irritation, which must by all means be removed as speedily as possible.

The above is intended for a sketch of the process of necrosis in one of its most frequent seats, viz. the outer (subperiosteal) layers of the compact sheath of a long bone; but it may occur in any situation—in the medullary canal, or central layers of the compact tissue, in flat or irregular bones, or the spongy ends of long bones; or again, the extent of the necrosis, or the situation of the part, may modify considerably the process of separation, i.e. the surgical aspect of the case. For example, even when necrosis is subperiosteal, and the process of separation normal, it may be in a part from which extraction is impossible, as on the inner surface of the skull, spine, pelvis, thorax, &c. The subperiosteal sheath is often wanting in the bones of the limbs when the soft parts have been extensively destroyed over the affected bone; and it is never formed in the skull, where necrosis is so common, nor in the cancellous bones, where, though less common, the disease is by no means rare. In such cases, when the dead bone is loosened from the living, it comes away of itself, or can be at once removed. Such a piece of dead bone, not confined by an invaginating sheath of new bone, is called an *exfoliation*. Again, it sometimes happens that the necrosed portion involves the whole thickness of the shaft of a long bone, and sometimes the whole length of its diaphysis; some instances even are exhibited in the museums where the epiphysis also has perished along with the entire shaft, though this is very rare.¹ Necrosis also sometimes attacks the epiphysis only, and even the deposit of bone which in early life forms the centre of ossification for the epiphysis.²

Each of these conditions is accompanied by noticeable peculiarities. When the whole thickness of the shaft is involved, especially in a bone, like the humerus, enjoying free and rapid motion, fracture is likely to follow on the completion of the groove, although this result may be obviated by the strength of the case of new bone. When the whole diaphysis is involved, the case assumes a graver aspect, since the extent of inflammation which is necessary for the formation of the new shaft, and the great suppuration thereby produced, suspends, or perhaps permanently abolishes, the functions of the limb. The muscles become matted together, the skin oedematous and penetrated by numerous sinuses, the parts below incapable of extended motion or energetic action; cases even are on record where the inflammation having reached the great vessels, has produced conglutination of the blood in both artery and vein, and consequent dry gangrene of the limb.³ In other cases either the ulceration around a sequestrum, or other disease of the bone, involves a large vessel, or the point of an exfoliating portion of bone is driven into the artery in some movement of the limb;⁴

² See the section on Epiphysitis in the essay on DISEASES OF THE JOINTS.

³ Museum of St. Bartholomew's Hospital, series i. No. 134.

⁴ Mr. Poland, in his essay 'On Rupture of the Popliteal Artery,' quotes one case of spontaneous hæmorrhage from that vessel in necrosis of the femur (a patient of Dr. Porter, *Dublin Journ.* vol. v.), and two others where the artery was wounded by a sequestrum during active movements of the limb (Dr. Byrön's case, *Med.-Chir. Rev.* vol. xxiv. p. 259; Dr. Jacob's *Diss. Med.-Chir. de Aneurism.* Edin., 1814). I have seen fatal hæmorrhage from the lingual artery in disease of the jaw, and from the aorta in caries of the spine. Mr. Stanley (*op. cit.*

and thus either a direct wound of the artery is produced (when the sinus of the diseased bone communicates with the laceration in the artery), or if no opening exists externally, a consecutive aneurism may possibly be established. In any case of such injury to the main vessels, when the diagnosis can be properly established, amputation would be indicated in the lower limb. In the upper limb the main arteries are separated from the bone by a mass of soft parts; and smaller vessels would hardly complicate the case, as they might be included in the incisions required to expose the diseased bone. In other situations attempts must be made to tie the ulcerated vessel; and if they fail, as they generally will, from the rotten condition of the parts, the trunk leading to it must be secured.

In cases of necrosis involving the whole thickness of a bone (*total* necrosis), when the seat of the disease is a large bone, such as the femur, life is in considerable danger; and as the patients are usually persons in whom some constitutional cachexia is present, and probably in an advanced stage, they frequently succumb. Still the dangers of amputation in these cases are so great, and the advantages of saving the limb so decided, that they are usually left to the reparative powers of nature. In small bones, such as the phalanges, amputation is indicated. In the upper limb large portions of the whole thickness of the shaft may be removed with entire success, and preservation of the motions of the extremity. In the essay on *Excision*, the indications for excision of the whole or parts of bones on account of necrosis, involving their whole thickness, will be further considered.

Central necrosis is usually an obscure complaint, and is hardly distinguishable by its symptoms from chronic abscess of the bone. In fact, as their symptoms are the same, so the same treatment is applicable to each of them. Deep-seated pain, throbbing, loss of rest, general debility, perhaps rigors and some amount of fever, with slight puffiness over the seat of the disease, and a little pain on pressure; these symptoms persisting for a considerable period without relief, notwithstanding that the appropriate constitutional and local remedies have been employed, indicate the necessity of making an exploratory incision at the seat of the inflammation, and, if the surface be found healthy, of removing it with the trephine in order to search for an abscess or sequestrum in the centre.

Mr. Marrant Baker¹ has called attention to the occasional occurrence of necrosis unaccompanied (at least for a very considerable period) by any suppuration. In the case which formed the text of Mr. Baker's paper, symptoms of disease in the femur had lasted ten weeks, and spontaneous fracture had occurred four weeks before amputation, which was performed at the hip, under the impression that the disease was malignant. On examination, it was found that nearly the whole shaft of the femur was necrosed, and the necrosed parts were separated from the periosteal bone in the greater part of the limb, yet no pus was found. In this instance, Mr. Baker believes that the necrosis was the result of chronic inflammation, leading to deposit of new bone, both on the periosteal and endosteal surfaces (a condition to which he gives the name 'intraosseous necrosis'), by which deposit the already defective circulation in the sclerosed shaft was obstructed, and thus the latter was made to die. He also gives other examples in which necrosis seems to have existed without any observed suppuration, and refers to a paper by Sir J. Paget on 'Necrosis of the Femur without External Inflammation,' *Clin. Soc. Trans.* vol. iii. 183. The fact is very important in a surgical point of view, since in these cases the dead bone may be so extensive, and so locked in by the invaginating sheath, as to be quite irremovable except by amputation; and again the resemblance to malignant disease is often very great.

Deep-seated necrosis often leads to suppuration, making its way to a free surface. This is very common in the long bones, and is a frequent cause of abscess and destructive inflammation of the joints. Necrosis may also attack a portion of the articular surface of one of the great joints of the body, although this is rare except as

p. 411) relates a case in which the capsule of the knee-joint was penetrated by the pointed end of the necrosed shaft of the femur.

¹ 'On Necrosis without Suppuration,' *Med.-Chir. Trans.*, vol. lx. 187. See also Colles, *Dublin Journ. of Med. Science*, Dec. 1878.

a complication of extensive strumous affection of the joint-surface. Limited necrosis of articular ends is, however, occasionally met with, and, like the previous affection, will set up abscess in the joint. The diagnosis of these causes of articular abscess must be sought in the essay on DISEASES OF THE JOINTS, and the indications for operative treatment in that on EXCISION.

In the flat bones, where they are formed of compact tissue, necrosis is an exceedingly common disease; but here, as has been before observed, the dead bone will usually exfoliate without invagination. The same may be said of the necrosed portions of irregular bones, which consist almost entirely of cancellous tissues (such as those of the tarsus), in which necrosis is by no means rare. Whole bones, or large portions of entire bones, of the tarsus, and sometimes, but less often, of the carpus, are found quite separate from all their attachments, and merely retained as foreign bodies among the soft parts. In such cases there is sometimes a little difficulty in making the diagnosis; since the dead bone has not the hard ringing sensation usual in necrosis of compact tissue, and the large size of the necrosed piece sometimes prevents it from moving under the probe. The case, therefore, simulates one of caries. A free incision will solve the question.

However, though the cancellous tissue is sometimes affected with necrosis, it should be remembered that this is exceptional, and that necrosis is an affection more peculiarly of the compact tissue, and especially of the densest bones. Thus the petrous bone is frequently necrosed, and has been known to exfoliate almost entire.¹

Treatment.—Hitherto we have been considering the usual method of separation; and as this is a long and tedious process, seldom completed under many months in the case of a large sequestrum, and often dating by years, it is not surprising that efforts should have been constantly made to anticipate the period of cure by cutting away the diseased bone. These, however, have hitherto resulted in disappointment. The process must be left to find its natural completion in the spontaneous separation of the dead bone from the living; and any attempt to effect this by operation, *i.e.* to detach the necrosed portion, and to cut it away from the living parts, only extends the area of the disease, and endangers the preservation of the limb. Special considerations, applicable to some regions of the body, such as the skull, may indeed induce a surgeon to operate on necrosed bone before it is loose, for the relief of matter pent up below it: such operations, however, are not undertaken with a view of curing the diseased bone, but of restoring the function of organs secondarily affected. Such has been the result of surgical experience up to the present time. I have, however, pointed out above (p. 292), that a sequestrum of limited extent may be dissolved out by the action of sulphuric acid, and thus the slow process of vital action necessary for its separation may be anticipated. In order to obtain success, however, in these proceedings, it is essential to know exactly the limits of the disease.

But when the sequestrum has separated and lies loose and invaginated in new bone, surgical interference is most necessary. There is perhaps no part of surgery in which the improvements effected in comparatively modern times have done so much to preserve life and limb, and to obviate pain, as in the treatment of necrosis. The invaginated portion of bone can never get out by any natural process: the very completeness and efficacy of the efforts which nature makes to preserve the continuity of the bone, and to restore its strength, effectually imprison the dead portion. Small pieces or granules of dead bone constantly exfoliate from carious surfaces; but when the sequestrum is of any considerable size, the cloacæ are never so large as to admit of the escape of the sequestrum through them, although sometimes they are very nearly large enough. Thus, in the Museum of St. Bartholomew's Hospital, there is a curious specimen,² in which a small piece of loose bone, just too large to get out of any of the numerous cloacæ which have formed around it, is found rattling about in its cavity as if in a dice-box.

The requisite operation consists in cutting down on the dead bone, and exposing

¹ *Path. Soc. Trans.* vol vii. p. 335. A similar case occurred at St. George's Hospital, under Mr. Prescott Hewett's care; Museum, St. George's Hospital, series ii. 99.

² Sub-series, A, No. 94.

it sufficiently to remove it. If the necrosis be superficial, nothing is required beyond turning back the soft parts, which have no connection with the dead bone, elevating the latter, and pulling it out with a pair of forceps. But, for the removal of an invaginated sequestrum, it is necessary to open the sheath by enlarging one of the cloacæ with the trephine, chisel, osteotrite,¹ or cutting forceps, until it is large enough to admit of the extraction of the piece. Sometimes, when the sequestrum involves a large portion of the shaft of the bone, it may be found impossible to get the piece away until a pair of cutting forceps or a trephine has been introduced through the enlarged aperture, and the dead bone divided. In the necrosis which so often attacks stumps after amputation, a ring-like piece may separate from the end of the divided bone. Its extraction is then a matter of considerable difficulty; but still, as there is a free opening on to the extremity of the dead bone, it may be accomplished with some little trouble. If a similar sequestrum should form on one of the long bones, involving a ferule-like portion of its surface, its removal would be still more troublesome, requiring free incisions on both sides of the limb: but I am not aware that such cases have been noticed in practice. A preparation in the Museum of St. George's Hospital (series ii. 75) shows a strip of necrosed bone winding spirally, for a considerable distance, round the shaft of the humerus.

It has sometimes been made a question whether the sequestra of necrosed bone can be removed by a gradual process of disorganisation and molecular decay. If this question be proposed as an essay in scientific pathology, there is no doubt of its great interest; but, viewed as a practical consideration in surgery, hardly any value attaches to it. Experiments on animals certainly appear to show the possibility of the removal of small pieces of excised bone reimplanted in the excision-wound;² and it is possible that, in the human subject, sequestra of bone may be to some extent eaten away by a process of absorption like that which sometimes removes the ivory pegs driven into bones for the cure of ununited fracture (see FRACTURE);³ but even allowing all upon this head which any one could reasonably deduce from such facts as these, we should still be justified in saying that the process is so slow, so uncertain, and so partial, that no account ought to be taken of it in surgery.⁴

It is therefore necessary, in every case in which a sequestrum forms, that a surgical operation should be undertaken for its removal. The word *sequestrum* is here used in its strict sense, to express a portion of dead bone contained in a case of new bone. An *exfoliating* portion of bone may separate and be thrown off by the natural processes, though it is usually necessary to facilitate its removal when loose by incisions.

As a general rule, the dead bone ought to be removed as soon as it can be ascer-

¹ Numerous instruments have been devised for the enlargement of cloacæ, and removal of the periosteal sheath in cases of necrosis, of which it is impossible here to discuss the value. Two of the most generally useful are Linhart's chisel, described by me in *Clin. Soc. Trans.* vol. ix. p. 122, and Marshall's osteotrite, an instrument resembling on a large scale the 'rosehead drill' used by dentists. By working this in a cloaca an opening large enough to admit the finger is rapidly and safely made.

² Heine, in *Gräfe und Walther's Journal*, Bd. xxiv. p. 527, quoted by Wagner, *op. infra cit.* p. 146.

³ A case showing this absorption very clearly has been put on record by Prof. Cleland, in the *Brit. Med. Journ.* for Feb. 22, 1868.

⁴ It may reasonably be doubted, also, whether the absorption said to have occurred in some of the experiments above referred to did really did place, or whether the whole thing was not a mistake on the part of the experimenters. Gulliver's experiments (*Med.-Chir. Trans.* vol. xxi.) show that portions of loose bone, thrust into the tissues of living animals, may remain an indefinite time without experiencing any absorption, as proved by careful weighing at the beginning and end of the experiment. Again, cases such as that quoted on p. 295, prove that a portion of bone, of no extraordinary size, may remain necrosed during a great part of a lifetime, and suffer no perceptible diminution in size. This is the case even when its mechanical connection with the rest of the body is not entirely destroyed. But surely when loose and separated from the living tissues it must be still less under the influence of the vital actions. In a paper by Mr. Savory, in the *Med.-Chir. Trans.* vol. xlvii., several experiments are described, showing that the absorption of dead bone driven into the living bones of animals, is proportional to the pressure to which it is subjected, a condition which hardly exists in the cases of necrosis that occur in practice.

tained to be loose; but it is not always easy to determine the question whether the bone is loose or not, since the growth of the periosteal sheath, or even the shape of the loose portion, and the arrangement of the parts around it, may prevent it from moving under the probe. In cases, therefore, where the disease has lasted so long that the separation may be reasonably expected to be complete, it is right to endeavour to remove the bone, even although the probe has not given decisive evidence that the operation can be carried out.

I would here call the reader's attention to the extraordinary power which bone, apparently necrosed, has of recovering itself, even after a long period of apparently total suspension of circulation. It is always interesting, and often astonishing, to watch the progress of vascularisation in exposed cranial bone which has long remained white, dry, and to all appearance lifeless. At the present time I have under my care a very young child, in whom an abscess on the scalp had been neglected till the whole affected portion of the scalp sloughed. When admitted into hospital, the child presented in the occipital region two large tracts of exposed bone—one about the size of a penny, the other somewhat smaller, separated by a very narrow bridge of granulations. The bone was white, dry, somewhat rough, and seemed perfectly dead. No treatment of any kind has been adopted, except water-dressing; but now, after about six weeks' residence in the hospital, the edges of skin have grown very considerably over the exposed bone, and the bridge of granulations has extended so as to cover more than half of the smaller piece, while, in almost every part of the bone still left exposed, fresh points of vascularity are showing themselves; and there really seems some prospect of the whole being revived without any exfoliation.

It is necessary here to say something respecting the agents, and the manner, of regeneration of bone after loss of substance from necrosis. In doing this, however, it would be impossible in an essay of this sort to go into the question with any approach to completeness; but it is hoped that enough will be found in the following paragraphs to illustrate the points necessary for practice. The student who wishes to learn more about the matter is referred to the works of Troja, Wiedmann, Flourens, Syme, and Wagner.

The most important agent in reproducing bone lost by necrosis is, without doubt, the periosteum; and this membrane is sufficient of itself to replace all the ordinary exfoliations and partial necroses which follow injuries, &c. The osteogenic properties of the periosteum, when in contact with the bone, have long been known—in fact, must have been apparent when the function of the membrane was first studied; and that periosteum, when separated from the surface of the bone, will still generate new bone, is no very novel discovery, since John Bell seems to have been perfectly well acquainted with the fact, and describes the formation of a bony cyst by secretion from the detached periosteum, around a collection of blood which had dissected off that membrane from the bone;¹ and the experiments of Syme and Stanley are well known. Lately the osteogenic powers of periosteum have been placed in a very striking light by the experiments of M. Ollier of Lyons.² He has shown that, in rabbits, portions of periosteum may be entirely detached from the bone, and pushed into the cellular tissue of the limb, or even grafted into remote parts of the body, or into the body of another rabbit, and that bone would be generated from the fragment of periosteum in this novel position. He has even succeeded in producing bone by such grafting of portions of periosteum kept for more than an hour out of the body.

- It is far from certain that any such results could be produced in man, since the conditions of all reproductions, and especially of reproduction of bone, are known to differ so much in man and animals; but, even if the vitality and osteogenic power of the periosteum be less in the human subject than in the lower animals, still it seems

¹ *The Principles of Surgery*, by John Bell; a new edition, by Charles Bell, 1820, vol. iv. p. 406. The author's view of the pathology is sufficiently dubious; but the case may be used to show that Bell knew that bone could be formed from the detached periosteum.

² *British Medical Journal*, 1880, pp. 398, 438; *Traité de la Régénération des Os*, Paris, 1867.

reasonable to infer, from observed phenomena, that that power is of the same nature ; so that these striking experiments may serve to fix more firmly on the attention of surgeons the importance of preserving the periosteum in cases where the reproduction of lost bones is in question. In all cases, then, where loss of substance in bone has taken place, or where the bone seems deprived of life, it is of the greatest importance that the periosteum should be preserved, a point which will be noticed again in the essay on EXCISION, in speaking of sub-periosteal resection.

The periosteum, however, although the most important, is not the sole agent in the reproduction of bone ; so that it may be confidently expected that bone will be reproduced in healthy subjects, even though the periosteum be extensively destroyed ; but the reproduction will not be so complete as if that membrane had been left. Such a process of reproduction may often be watched in cases where the soft parts have sloughed after scalp wounds, and have left the cranium exposed.¹ The accident will often be followed by exfoliation from the surface of the bone ; granulations then shoot up from the bony surface so exposed, and these are joined by others which advance from the soft parts in the neighbourhood : a fibrous cicatrix is formed which can be felt gradually hardening and ossifying. If an opportunity occurs for examining it after the lapse of some considerable time (say half a year), it will be found that the fibrous tissue of the cicatrix is ossifying at its deepest part, and scattered granules of bone will probably be met with at various parts of the cicatrix.

This process may go on even when the bone and periosteum have been removed by operation, as in the wounds of resection,² but is much more active when previous inflammation has been excited in the medullary tissue, and surrounding soft parts, during the action necessary in order to eject a piece of necrosed bone. In fact, speaking generally, the process of reproduction after necrosis is beyond comparison more active than after injury or operation. Thus, when necrosis has preceded the operation, whole bones of the forearm have been removed, and yet a useful limb has been preserved.

In a case which I had an opportunity of seeing, in which Mr. Savory removed the entire shaft of the radius on account of necrosis, leaving the articular ends,³ the bone had grown from each of these ends to so great an extent that in eight months after the operation there remained an interval of only an inch and a half, and this appeared to be gradually, though slowly, contracting. This and several similar cases will be found quoted in Wagner's treatise above referred to, and may serve as an encouragement for boldness in our attempts to save limbs after extensive necrosis.

The exfoliation of diseased portions of bone—such, for example, as takes place so frequently in the course of extensive strumous disease, when a portion of the ulcerated surface is cut off from the rest, and therefore perishes—is not generally accompanied by any of that reparative effort which forms part of the process in a more healthy condition. The mere presence of necrosis in such affections is of comparatively little importance ; possibly the removal of the dead part may be advisable (but only if it can be done without much violence), but the operation cannot be expected to cure the disease, since the necrosis is not its cause, but its effect. Nevertheless considerable improvement may, in appropriate cases, be expected to follow on the removal of the dead portion, which must always act as an irritant ; and the exposure of the carious surface is also very frequently the starting-point of a more healthy action. Hence, when bone is felt exposed and dead, it is usually advisable to endeavour to remove it, even although the surface around it is known to be carious.

The above description applies to necrosis in its more usual form. But, besides this common chronic form of the disease, an affection which deserves the name of *acute necrosis* is sometimes, though not very often, met with. The destruction of all the soft parts surrounding a small bone, as a phalanx in acute neglected whitlow, will of course lead to the exfoliation of the whole of it, and to this affection the name of acute necrosis is sometimes given. There is nothing, however, in the patho-

¹ See Wagner, *On Repair after Resection of Bones* (New Syd. Soc.), Appendix, p. 241, for a case in which this form of reproduction is well described.

² See Wagner, *op. cit.* p. 156.

³ *Ibid.* p. 243.

logy or treatment of such a disease to call special attention to the bone. The rapid and tensive inflammation threatens other parts of equal importance—the joint, the tendons, nay, in some cases even the skin—with destruction; and the free evacuation of the products of the inflammation is the only measure from which any good can rationally be expected. But there is a less known class of cases in which larger bones are involved in rapid destruction, without known cause, or from causes apparently quite inadequate; and such cases involve not merely local mischief, but very grave danger to life. Many such cases of rapid necrosis are the result of that diffuse inflammation of the periosteum, or medullary tissue, which has been described above; but in others which I have had an opportunity of seeing, I have failed to detect such a cause for the death of the bone, or indeed any cause to which so extensive and so universal an action could reasonably be ascribed.

Such a case was the following. A stableman was admitted into St. George's Hospital on account of disease in one foot. The history was obscure, but it seemed certain that little more than three weeks before his death the foot was comparatively well, as it was to an injury supposed to have been received two days before his admission, in running violently down the stable-yard, that the disease was attributed. There was cedema, swelling, and pain over the dorsum of the foot; and this condition was attributed to diffuse cellular inflammation, and treated by superficial incisions, which did not penetrate the periosteum. The man died, with symptoms of pyæmia, but no secondary abscess, twenty days after his admission. On examining the foot, all the tarsal bones were found loose, and grating on each other like stones in a bag; the cartilages between them had almost entirely disappeared. On section, the bones were of a dark-grey hue, and some slight trace of pus was seen here and there in the interior, but no such distinct indication of inflammation of the lining membrane of the cancelli as to deserve the name of osteo-myelitis; nor was the periosteum thickened, vascular, or separated from the surface of the bone by either lymph or pus in any appreciable quantity. The surfaces of the bones exposed by the removal of the articular cartilages were ulcerated, but not deeply. The bones were of their natural consistence.

Is such an affection as this amenable to any treatment? This seems doubtful, if it be conceded that cases of acute necrosis really exist in which the affection is different from diffuse periostitis. In the latter affection timely incisions may succeed, as has been already said, in checking the effusion and restoring the nutrition of the bone; but if the whole bony tissue be involved at once, what agency can be reasonably expected to restore it to health? It is clear that the main question in such a case is, whether the patient's powers will endure the strain of the disease, so that the bone may be cast off, and he may have the chance of its reproduction, or whether amputation will give him a better prospect of life. But the prognosis of an amputation undertaken under such circumstances would be in the highest degree unfavourable, since the condition of system in which such grave results can follow from such trivial injuries leaves little prospect of bearing up against so serious an injury as the removal of a limb; and the tendency to pyæmia is so strong that it is impossible to say that that condition of the system may not be actually present, though latent, when the operation is done. It will therefore, in most cases, be judged better to support the patient's strength by a liberal allowance of tonics and opiates until the graver dangers have passed away; and then, if the usefulness of the limb is hopelessly destroyed, to remove it when the patient has rallied from the typhoid condition in which the disease commences. Incisions may not have the power of averting the death of the bone, but they ought to be made to an extent sufficient to liberate all tension, and that for two principal reasons—partly in order to avoid sloughing of the periosteum, and consequent destruction of the nidus in which the new bone is to be formed, partly to provide drainage and a ready way for the pus, which must form, to escape, and partly for the examination of the bone and for its eventual extraction.

Acute necrosis, whether resulting from diffuse periostitis or not, may be treated by the extirpation of the whole bone so affected, a very free incision being made through the periosteum, which will be found completely separated from the bone, and the bone being, if necessary, divided by a chain-saw passed underneath it. In cases of necrosis of the entire diaphysis of a long bone, a slight twist with the lion-forceps will detach the dead portions from the epiphysal lines above and below.

In this way I removed successfully the whole shaft of the tibia (seven and a half inches long), at the age of ten, one month after the commencement of acute periostitis, with very successful results.¹ I think, when we have clear reasons for believing that the necrosed bone will be found loose, its early removal is most desirable, and liberates the patient from great dangers, both in the present, from the acute surgical fever kept up by the irritation of the diseased bone, and in the future, from the risks incident on the numerous and severe surgical operations which will probably be necessary for the removal of so extensive a sequestrum. I do not recommend the operation when a portion only of the diaphysis has perished, and has not yet separated. The old idea that it is necessary to wait in these cases for the formation of a periosteal sheath of bone, is sufficiently refuted by my cases and that of Mr. Joseph Bell, which show that even in so large a bone as the femur a great portion (and I do not see why not the whole, if such a case should occur) of the entire circumference of the shaft may be removed, and the limb be left perfectly flail-like after the operation, and yet entire consolidation and perfect usefulness of the limb may finally result.²

CONSTITUTIONAL AFFECTIONS.

Scrofula in bone.—There are two forms in which scrofulous affections of bone are met with: viz. either a deposit of tubercle, or a low inflammation of the osseous substance; and there is good reason for considering the former as a consequence, or effect, of the latter. Let us, then, first consider the peculiar or distinctive characters of scrofulous inflammation of bone.

A scrofulous bone, when examined in the early stage of the disease, is soft, light, and oily; sometimes more highly charged with blood than natural, and occasionally (though only rarely) presenting a deposit of tubercle in its interior. Bones in this condition are constantly met with after the removal of scrofulous joints: the substance of the bone is easily cut with a knife, and the cancelli are large, and charged with a red jelly-like mass of debris. The inflammation readily passes into ulceration, or caries, and the bone then exhibits on its surface a number of minute pits or depressions, from each of which the ulceration extends, so as to communicate with those around, until an extensive worm-eaten surface is exposed,³ soft and rotten on its exterior, bleeding readily, and giving exit to a foul-smelling ichorous pus, in which pieces of decomposed bone can be felt as gritty particles under the fingers. The periosteum becomes detached and thickened, and is gradually converted into a gelatinous mass of granulations.

The minute changes in the ultimate tissue have been ably described by Dr. Black, in a series of researches to which my own observations lead me to assent. The cancelli are dilated, and they, as well as the lacunæ and canaliculi, are filled with exudation. Occasionally, minute projections of bone from the walls of the cancelli indicate an attempt at the reproduction of bone, and that healing by sclerosis which has been already described as one of the usual events of healthy inflammation. The leading features, then, of the pathological anatomy of strumous inflammation are the same as those of osteitis in general; and the only distinctive anatomical peculiarity consists in the nature of the exudation, which chokes up the canals of the bone. Dr. Black has given several analyses, tending to establish these four conclusions: that tuberculosis gives rise (1) to a considerable increase of fat in the diseased bone; (2) to a large diminution of the salts of lime; (3) to a diminution of the organic matrix; (4) to an increase in the soluble salts. For the details

¹ *Lancet*, 1866, vol. i. p. 340. See also *Surgical Treatment of Children's Diseases*, 2nd edit. p. 301, *et seq.*; *St. George's Hospital Reports*, vol. x. p. 500; where other instances under my own care are related; also a case by Mr. Joseph Bell, *Brit. Med. Journal*, May 2, 1868, very similar to a case of mine in the femur, but more extensive. Many other cases have since been operated on; indeed the operation has now become a recognised one.

² An interesting example of the entire regeneration of the clavicle after its extirpation will be found in the New Syd. Soc.'s *Biennial Retrospect*, 1867-8, p. 262.

³ For the appearance of scrofulous ulceration in the macerated bone as contrasted with simple ulceration, see figs. 47A, 48, p. 289.

of the analysis, the reader must be referred to the original treatise.¹ They serve to illustrate the fact, that strumous is distinguished from common inflammation by the softness, lightness, and oiliness of the affected bone; to which may be added, the greater extent of diffusion of the morbid changes.

The superficial caries, during the mere presence of which, the bone, if the affection be not very extensive, is possibly still in a curable state, spreads gradually inward, and then the condition of the bone passes beyond the possibility of repair. Large abscesses form, and the whole cancellous extremity, or the whole bone, if it be one of the cuboid bones of the tarsus or carpus, is converted into a cavity bounded by a thin shell of osseous matter, and containing bony substance, either in mere débris, or so soft that it will crumble away in maceration. These abscesses are seldom accompanied by that thickening of their walls from periosteal deposit which takes place in simple osteitis; still, at some distance from the seat of profuse suppuration, fresh deposit is sometimes found thickening the bone, or producing anchylosis in the less movable joints. Necrosed portions of larger or smaller size are often found, but no 'sequestra' in the proper sense of that term, as signifying necrosed portions invaginated by new bone.

Such are the anatomical characters of scrofulous inflammation of bone.² The other common development of that diathesis in the osseous system consists in the deposit of tubercle either circumscribed or diffused. Circumscribed tubercle³ (much the rarer form) seems most common in the skull, deposited on the outside of the bone beneath the periosteum (the strumous node); and next to this its favourite locality is in the cancelli of the joint-end of some bone, generally the tibia. No inconvenience seems to be produced by such tubercle till it softens; and then, if situated in the articular end of a bone, it usually makes a passage into the neighbouring joint and destroys it; if on the skull, the softening of such a tubercle forms a cystic abscess difficult to heal, bordered by indurated cellular tissue, with cold, bluish edges, and leading to exposed and roughened bone, which, however, has not the peculiar feeling of necrosis, and is not at first dead, although it is liable to become so. The deposit of diffused tubercle is more common in the shafts of the long bones. It fills up the cancelli, appearing as a nodulated, or granular, yellowish

¹ *On the Pathology of Tuberculous Bone*, p. 32. Edinb. 1859.

² Tubercle in bone is, in any view of the case, rare. Rokitsky's statistics give a low place to the bony system as a seat of tubercle; though they place the bones and periosteum considerably above the testicle and epididymis, which is hardly in consonance, I believe, with the experience of most surgeons. But the nature of the deposit generally spoken of as tubercular is the subject of much difference of opinion among different pathologists. Dr. Wilson Fox says: 'These limitations of tubercle have proceeded so far, that, if the exclusion of the different forms from the category of tubercle, proposed by various pathologists, were simultaneously carried out, tubercle would—not unfortunately, cease to exist—but would certainly have no longer any place in our nosologies; for nearly every pathological product hitherto ranked under this title, from the grey granulation to the yellow granulation and the cheesy infiltration, is by some authority or other excluded from the category of tubercle.'—*Artificial Production of Tubercle*, p. 22. My opinion is, that many of the deposits which are usually regarded as tubercles in bone, are masses of inspissated pus mingled with other inflammatory products; and that, rare as tubercle in bone is generally said to be, it is in reality still rarer. Mr. Macnamara, on the other hand, for whose opinion I have a sincere respect, believes that the deposit of inflammatory material found in the bones of tuberculous subjects differs in no respect from the deposits of tubercle which may be found in their viscera, and looks upon tubercle in bone as a tolerably common appearance. See the Fourth and Fifth of his recently published *Lectures on Diseases of Bones and Joints*. Some of the German pathologists appear to regard every inflammatory production in which 'giant-cells' and 'a reticulum' can be found as tuberculous, and then go on to assume for this tubercular product an auto-infecting property. All this however appears to me to rest on the slenderest basis of fact (see Treves on SCROFULA, ch. iii. and iv.) Mr. Croft, in relating some cases classed by him as tubercular affections of the articular ends and synovial membranes of joints, in *Path. Trans.* vol. xxxii., has with the caution of experience allowed that we want much more extended information. Much of the present difference of opinion, however, depends on the view taken of the nature of tubercle. The Germans for the most part regard it as a specific, and infecting new growth; the English, generally, as the outcome of chronic inflammation under certain constitutional conditions. See Mr. Treves's essay on SCROFULA, in vol. i.

mass of soft consistence, and extends frequently along the whole length of the shaft. My own impression is that this diffused tubercle less frequently and less rapidly softens than the circumscribed; but exact information on this point is wanting. It should be remembered that when the shaft is attacked by this or any other form of disease, the extremities usually escape, and *vice versa*—a matter of great importance in the treatment of diseases of the joints.

It has occurred to me, though hitherto only on two occasions, to meet with a particular form of ulceration, which was in one case certainly,¹ and in the other probably, connected with scrofula.

Numerous pits were found on the articular surface, varying in depth, but confined to the epiphysis, with sharp edges, and curdy purulent contents. Their openings into the cavity of the joint were clearly punched out of the cartilage, and all the cartilage around was quite healthy. A few small granules of bone were met with among the contents of the cavities. In one of the cases, when the bones were examined, there were found several spots of vascular and softened tissue beneath the surface of the bones, evidently the commencement of similar pits. There was no trace of tubercle. The thigh was amputated, and the patient recovered for a time, but soon died of phthisis. In the other case, the patient, a boy under the care of Mr Thomas Smith, recovered after excision of the knee, and remained long afterwards in good health.²

I believe this pitting or spotted ulceration of the articular ends of bones to be one of the forms of scrofulous disease, and to be indistinguishable from its other forms before dissection. It presents a very favourable condition for resection, from the strict limitation of the disease to a very slight depth below the surface.

Symptoms.—Of the symptoms of scrofula in bone little need be said here. The general symptoms of the diathesis, added to an indolent swelling of some bone, lead to a diagnosis not to be mistaken. The swelling is composed partly of the engorged soft tissues, and partly occasioned by real enlargement of the bone. The colour is usually white and pasty,³ and the swelling indolent; but sometimes, when the inflammation is higher than common, and suppuration imminent, redness and pain may be present. When suppuration has been effected, the pain generally subsides, and the functions of the part are more or less completely regained, even when the bone is destroyed to a considerable extent.

Treatment.—The treatment of scrofula in bone offers little that is peculiar. For local treatment perhaps the most important indication is to keep the part at rest by splints and bandages during the prevalence of inflammation. Local depletion should be cautiously used while there is pain, tenderness, and superficial redness, or the part may be enveloped in a large warm poultice or fomentation. When inflammation is not apparent in the soft parts, but there are signs of its presence in the bone, it will be necessary to use counter-irritation by a light application of the actual cautery by blisters or by caustic issues; or in less severe and more chronic cases by means of the tincture of iodine, or other stimulating application. When irritation has subsided, pressure by means of strapping will be found very serviceable, both in ensuring rest and promoting absorption, and the local application of mercury (Scott's bandage) may be combined with this. By these simple measures, with judicious constitutional treatment, most of the cases of strumous inflammation, which are seen before the occurrence of suppuration, will be brought to a favourable issue.

When the suppuration is once established, it is better to procure exit for it by small incisions, and to use every precaution to prevent the denudation of fresh portions of bone. The question, however, of the early or late opening of abscesses connected with strumous bone is one on which a good deal of difference of opinion very naturally exists, and which is best determined in each individual case. If, however, the abscess be near an important organ, as a joint or serous cavity, then

¹ A notice of this case will be found in *Path. Soc. Trans.* vol. x. p. 217.

² This is figured in the work, above referred to, *On the Surgical Treatment of Children's Diseases*, p. 488.

³ The 'white swelling' of old authors was named from strumous disease of the joints, though many other affections came to be included under the term.

undoubtedly no time should be lost in evacuating it. The use of Lister's method has seemed to me extremely advantageous in these cases. When the bone is exposed through the opening of an abscess, its condition should be thoroughly investigated, once for all, with the probe, in order to judge of the necessity for operative interference; but nothing is more mischievous than repeated meddling with diseased bone. The general indications for operations upon bones affected with strumous caries, and the form of operation indicated, will be the same as in caries depending upon other causes; but the prognosis will be less favourable than when the constitution is unaffected, and therefore operations should be undertaken with more caution. Operations on these cases will usually succeed or fail according as scrofula has attacked the viscera or no, and according to the extent of its diffusion through the system; but even after a successful operation the patient is by no means secure against a relapse in some other part. It has lately become common to perforate bones affected with scrofula either by means of a small trephine or a drill, and to keep the canal so made constantly drained, the whole proceeding being performed with antiseptic precautions. If a neighbouring joint is affected, it should be freely opened at the same time and drained. I would refer to Mr. Macnamara's work, p. 115, for instances of the success of this practice.

For the general treatment the reader must be referred to the essay on SCROFULA.

Closely allied to tuberculosis is the affection designated Lymphadenoma, or Hodgkin's disease; and although little is known of the affection of the bones in this disease, yet Mr. Macnamara (*op. cit.* p. 123) has recorded a case of lymphadenoma in which an extensive deposit of lymphoid or fibrocellular material was found in the cancellous tissue of the tibia, very similar to that which existed in the cervical glands. No mention is made of any symptoms connected with this condition of the bone, nor is it stated that any other bones were examined. The case, however, is interesting as calling attention to another of the widespread influences of this destructive affection.

Syphilitic affections of bone.—The chief phenomena of the syphilitic affections of bone are described in the essay on SYPHILIS; it will therefore only be necessary here to go a little more into detail as to the anatomy of bone affected by syphilis, and the means by which the disease is to be diagnosed. As the general treatment of syphilis is laid down in Mr. Lee's essay, only the local treatment of its manifestations in the osseous system will be dwelt on here.

Syphilitic affections are those in which the existence of a chronic limited inflammation of the periosteum alone is most clearly proved, if indeed such inflammation be not peculiar to syphilis. Strumous nodes (as we have just remarked, p. 304) are formed by scrofulous matter confined between the carious bone and its periosteum, and are due to an affection of the bone; but the true node, that which follows syphilis, is caused by the effusion of lymph between the bone and the periosteum, and is due to inflammation of a limited portion of the deep layers ('sub-periosteal blastema') of the latter. Hence it is of a different signification from that of a strumous abscess; for, while the latter is merely a consequence of diseased bone, and necessarily involves corresponding loss of substance and the slow processes by which alone an ulcer (and more especially a strumous ulcer) in bone can be healed, the syphilitic node is itself the starting-point of the disease in the bone, and if early and properly treated, the whole organ can be restored in a short time to a state of health. But, although in a node the inflammation is usually limited to the periosteum, it is not always so. Numerous preparations show thickening of the substance of the bone beneath nodes,¹ proving the implication of the deeper structures, and therefore a state of disease which, though still curable, may be expected to be more obstinate than mere periosteal effusion; and if the skull be examined in the situation of a node, some roughening of its outer table may generally, perhaps

¹ St. Thomas's Hospital Museum, series c. No. 54.

always, be discovered. The progress of nodes, when they are not absorbed under appropriate treatment, is in one of two directions; either the subperiosteal effusion ossifies, or it softens and gives rise to caries, accompanied usually by suppuration. The former event is commoner on the tibia, the latter on the skull. The indisposition of the pericranium to form new bone is a well-known fact in pathology, nor am I aware that the formation of new bone in syphilitic nodes of the skull has ever been proved, though new bone may be sometimes found deposited on the outer table of the skull in the neighbourhood of large ulcers; ¹ in nodes of other flat bones also, ossification, if it occurs, is rare. Many nodes appear so hard as to be pronounced osseous; but the feeling is often deceptive, since the tense and thickened periosteum raised by semi-solid effusion gives a sensation hardly to be distinguished from that of a bony swelling. Therefore, in a hard node which is of no long standing, treatment for its removal may be confidently recommended, and all the more if the swelling be situated on a flat bone. On the tibiae nodes are prone to ossify, and then the deeper ossified part remains as a permanent irregularity on the surface of the bone; but the unossified portion may often be dispersed by appropriate measures. When a node softens, and the question occurs whether pus has formed, the case ought to be carefully examined, in order if possible to determine the point. The principal indication of the presence of pus is the shining, tense, and thinned condition of the skin. It is important to obviate more destruction of the skin than is inevitable on the bursting of the abscess, since such sores are very difficult to heal, and in some cases appear incurable. The best way is to make a very small puncture, and close it after drawing off the pus. Frequently, under the proper treatment, the soft parts will adhere again to the bone with very slight or no ² exfoliation. It is especially in these cases of abscesses communicating with the surface of a bone that I have found the treatment by carbolic acid, recommended by Mr. Lister, most successful. In several cases under my own care where I have had either positive proof or the strongest reasons for concluding that the abscess was connected with diseased bone, I have found the abscess heal readily and without exfoliation. Many others have also been put on record by Mr. Lister and other surgeons. Very commonly, however, the formation of periosteal abscess after a node is followed by the exfoliation of most of the subjacent bone. Syphilitic nodes are usually precoded, and always accompanied, by more or less of dull aching pain in the bone, especially liable to exacerbations at night; or this 'syphilitic rheumatism,' as it is sometimes called (the *douleurs ostéocopes* of French authors), may be the only symptom referred to the osseous system during the progress of the secondary affection.

When the syphilitic cachexia is further advanced, the whole bone or a great part of it may be diseased through its entire thickness, leading to chronic osteitis, and terminating in sclerosis, or what is sometimes called 'hypertrophy' of the whole thickness of the bone. I am not aware of any distinction which could be drawn between such instances of chronic inflammation and those arising from non-specific causes, except that which is founded on the presence of concomitant and preceding syphilitic symptoms in other organs.

Still more grave and more obstinate developments of tertiary syphilis in the bones are those carious and necrotic affections (ulcerative or gangrenous) which so often attack the skull, the bones of the face, and the superficial long bones, in persons much reduced by excesses, or by the injudicious administration of mercury. In former times, under the horrible system which prevailed in the 'foul wards' of the great hospitals, where every person labouring under any disease supposed to be caused by promiscuous intercourse was compelled to take mercury to salivation, the ravages of syphilis on the bones were dreadful; and it is to this system that we owe

¹ Even here it is in most cases doubtful whether the deposit has been formed outside the skull, or whether the thickening is not produced by deposit within the diploë expanding the outer table; for deposit in the diploë is exceedingly common. See below on the 'tuberculated' form of syphilitic ulceration in bone.

² See Parker, *Modern Treatment of Syphilitic Diseases*, 4th ed. 1860, p. 291.

many of the preparations of syphilitic caries and necrosis preserved in our museums. But there seems no reasonable doubt that such affections do also occur in persons who have never taken mercury,¹ especially when the disease has been allowed to go on unchecked, and the constitution is at the same time enfeebled by alternations of debauchery and hardship, as is the case sometimes with sailors, and more frequently with prostitutes.

The diagnosis of syphilitic affections is usually easy from the history of infection and the presence of other symptoms; but it may in some cases be obscured by the patient's unwillingness or inability to reveal the history of the original disease. Thus the pains in the bones may be referred to rheumatism; but here the diagnosis can in most cases be easily established by observing that rheumatic pains in the bones are generally accompanied by affections of the thick fibrous structures (muscles or fasciæ) and of the joints; or, if the rheumatic affection be more acute, the urine and sweat will probably furnish indications of the nature of the disease. When nodes have made their appearance, the diagnosis is usually easy, the only question

FIG. 50.—Syphilitic Ulceration of the Annular variety. (Museum of the Royal College of Surgeons, No. 635.)

lying between syphilis and struma, since rheumatic periostitis is, as we shall see, more diffused. In the absence of history, the concomitant symptoms will guide us while the skin is unbroken; and after pus has made its way to the surface, some assistance may be derived from the nature of the secretion. Syphilitic caries and necrosis (as is observed in the essay on SYPHILIS) are not primary affections of the bones, but are the result and termination of nodes, or of inflammation of the bones, or of ulcerative affections of the soft parts around the bone, as in the palate, and therefore have been preceded by a long course of symptoms, during which the diagnosis is usually established. If not, it rarely presents any difficulty, since the traces or the presence of other symptoms of constitutional syphilis can hardly fail to be recognised.

An interesting comparison has been made between the forms of syphilitic ulceration in bone and those of syphilitic eruption on the skin. Specimens of rounded ulcers may sometimes be met with, especially on the skull-cap, which bear a strong resemblance to the rupial ulcers so frequent in an advanced stage of constitutional

¹ See Parker, *op. cit.* p. 281.

syphilis. A small round spot of ulceration is seen, where the surface of the bone is worm-eaten from the presence of numerous minute depressions, and in some cases the bone around this worm-eaten central portion is marked by arborescent grooves, the traces of increased vascularity. Later on, a circular trench is marked around the worm-eaten spot; and as this widens and deepens, it undermines and finally chisels out the piece, which separates as a sequestrum, and then the bone scars over, leaving a rounded depression, much larger than the original spot, the surface of which is rather glazed and a little vascular, and the bone below it a good deal hardened. In well-marked specimens, these *annular* ulcers, as they are termed by Sir J. Paget, fig. 50, look very characteristic, but in less advanced cases, especially before the surrounding trench has formed, or again at a late period when cicatrization has obliterated some of the more distinctive characters of the ulcer, it seems

FIG. 51.—Syphilitic Ulceration of the Tuberculated variety. (Museum of the Royal College of Surgeons, No. 632.)

FIG. 52.—Syphilitic Ulceration of the Reticulated variety (Museum of the Royal College of Surgeons, No. 630.)

impossible to distinguish it from a scrofulous or other lesion. The other characteristic form of syphilitic ulceration is the *tuberculated*, fig. 51, which appears to commence by a tubercular thickening of the external wall of the bone, recalling the syphilitic tubercle so common on the skin of the face, &c, and due not to periosteal deposit, but to chronic inflammation of the compact tissue itself. This inflamed bone soon becomes dotted over with numerous little pits or depressions, which coalesce and form ulcers, usually oval or round, penetrating deeply into the interior of the bone. Besides these, Sir J. Paget has described a third form of syphilitic ulceration, the *reticulated* (fig. 52) in which the disease appears first to show itself in the form of a network of periosteal deposit, which is liable to perforation by ulcers subsequently forming and assuming the annular type, of which latter, therefore, the above may be regarded as a variety. Of the two kinds of syphilitic ulcer, the annular appears to me the more characteristic; but I do not believe that either is so distinctive of the disease as to enable us, with anything like certainty, to infer the previous

constitutional affection from examination of the affected bone; nay, I have known pathologists of the greatest experience refuted in such attempts by the subsequent discovery of the history of the preparation.

The accompanying figures represent characteristic examples of these various forms of syphilitic ulcer; and by comparing them with those of simple, strumous, rheumatic and malignant ulceration, which will be found at pp. 289, 312, 321, the reader will be enabled to see at a glance, much better than by verbal description, the differences of these affections as shown on the macerated bone.

Any of these forms of syphilitic ulceration may affect the bone so deeply as to penetrate its whole thickness. Thus in the Museum of St. Bartholomew's Hospital is a specimen (A 34) of a clavicle in which the bone has given way (probably after death) in consequence of penetrating ulceration attributed to syphilis. Spontaneous fracture of a long bone, however, from penetration by a syphilitic ulcer is extremely rare; while penetration of a flat bone, especially of the cranium, is still a pretty frequent circumstance, and used to be an ordinary result of syphilis. In the greater

FIG. 53. Penetrating Syphilitic Ulcer. (Museum of the Royal College of Surgeons, No. 636.)

number of such cases no serious mischief follows; the dura mater is exposed on the separation of the necrosed central part of the ulcer, but soon gets covered over, so that its pulsations are no longer visible, and in a little while the gap will be filled up by fibrous tissue. In rare cases, however, pressure upon the brain is produced either by matter confined between the skull and dura mater, or by ulceration laying open a branch of the middle meningeal artery and causing hæmorrhage.

Treatment.—The treatment of constitutional syphilis has been already described, and it has been shown that at one period or other of the disease a prolonged and sufficient exhibition of mercury will be necessary for a cure. To this general rule the affections of bone form no exception, for although some of them are usually found accompanied by so profound a cachexia, so complete a prostration of the whole system, that mercury is inadmissible, it will also be found that such affections do not admit of cure. Iodide of potassium often acts, however, upon the earlier affections of the bone and periosteum like a charm, and the symptoms soon disappear; but those whose experience in the treatment of syphilis is most extensive¹ believe that the improvement is not permanent, and that for the entire eradication of the constitutional affection a mild but prolonged course of mercury (for which the calomel

¹ See the essay on SYPHILIS, and Parker, *op. cit.* p. 289.

vapour-bath is the most appropriate agent) ought to be insisted on. The local treatment of bone inflamed from syphilis presents several interesting questions. Nodes will usually be benefitted by blisters, or if the bone seem to be more deeply affected, by the persevering use of mercurial ointment, strapping with the empl. hydr. cum ammoniaco, iodine paint, &c. But when the pain in the inflamed bone is constant and very distressing, it is quite justifiable to divide the periosteum by a free incision; and then, if nothing is found to account for the tension and to hold out a prospect of its relief, a trephine may be applied to the bone itself, and its medullary canal laid open.¹ If symptoms of cerebral disturbance make their appearance in the course of ulceration of the cranium, the application of the trephine has sometimes been successful in preserving life; but, on the other hand, it is not to be denied that it has sometimes produced or hastened death. The proverbial obscurity of all cranial affections ought, I think, to make us cautious in adopting so extreme a measure as trephining the skull, unless in a patient whose state is otherwise evidently hopeless. Epileptic convulsions, even with slight symptoms of paralysis, are hardly a sufficient indication for the operation; but the experience of Mr. H. Lee² has shown that in some cases the removal of the diseased bone has been followed by the healing of ulcers which had previously been obstinate; and it seems that the removal of the outer table only, when it is dead, and appears to be keeping up irritation, is a safe practice.

The treatment of fissures and defects of the palate from syphilitic necrosis will be found discussed in the essay ON DISEASES OF THE MOUTH.

Rheumatic affections of bone.—It is extremely difficult to be certain of the existence of any specific affection of bone due to the rheumatic diathesis.³

I would not be understood, however, to deny the existence of an affection which deserves to be called 'rheumatic osteitis.' The condition of the articulating extremities of the bones in cases of osteo-arthritis is very peculiar, and can hardly be explained by any theory except that of some constitutional peculiarity in the disease, since neither the age of the patient nor the mode of causation of the malady offers any constant features which can account for the singularity of the affection of the bone. That which is most characteristic in all those cases which appear to be rheumatic, is their very slow course, and the great length of time during which inflammation may be present without either caries or necrosis.

The chief features which are distinctive of rheumatic inflammation of the bones are, the extensive deposit of bone in the fibrous structures around, the condensation and thinning of the shell of the bone, the rarefaction and partial absorption of its interior, and the consequent change of shape which parts containing much cancellous tissue, such as the articular heads and necks of long bones, suffer. In the articular disease the new bone is found, to a great extent, in the ligaments and other tissues distinct from the periosteum, and thus forms what Dr. Adams calls 'additamentary bones,' which have been so often mistaken for portions fractured off the bony prominences, near which they may be situated, and remaining ununited. I shall adduce some reasons for believing that many of the specimens in which portions of bone have been found near the shafts of long bones, but movable upon them, and which have been thought to be instances in which exostoses had been fractured at their base, may be of the same nature.

In the Museum of the Royal College of Surgeons, Sir J. Paget has classed some specimens 'as 'rheumatic ulceration,' in which, along with these appearances on the shaft of the bone, ulceration is seen invading the newly-formed periosteal deposit. One of these preparations will be found represented in fig. 54. In any case, the occurrence of nodes, and more or less of inflammation of the wall of superficial bones

¹ Parker, *op. cit.* p. 283.

² *Proceedings of the Med.-Chir. Soc.* vol. iii. p. 283.

³ The disease now commonly called 'chronic rheumatic arthritis' or 'osteo-arthritis' is regarded by some authors of credit as originally a disease of the bone. It is described in the essay ON DISEASES OF THE JOINTS.

⁴ Nos. 626, 627, 627A.

in cases of rheumatism, is a sufficiently probable event; but it is a complication which must be treated on general principles. The nodes do not affect the limited extent and rounded outline of those due to syphilis, but are irregular swellings of

FIG. 54.—Rheumatic Ulceration of Bone. (Museum of the Royal College of Surgeons, No. 627.)

the periosteum, involving a considerable extent of the surface, and probably some of the thickness of the bone.

As to the treatment of the rheumatic affections of bone, nothing need be said here, since all that is necessary to add to the general treatment of osteitis will be found in the essay on DISEASES OF THE JOINTS, to which essay I must also refer for the affection of the articular ends of the bones, which has been described by Charcot as occurring in the course of locomotor ataxy.

Mollities ossium.—The peculiar condition of the bones which is known by the name of mollities ossium, or malacosteon, is one which is very rarely met with. In the female pelvis, as a cause of difficulty in parturition, it is less rare than under other circumstances, and demands the special attention of the obstetric surgeon; but in this place we have only to consider the disease in its pathology and general surgical bearings.

The pathology of mollities is far from being satisfactorily established; and there can be little doubt that this has arisen, in great part at any rate, from the fact that authors have confounded

several different conditions under the same name. Some, indeed, make no distinction between mollities and fragilitas ossium; while others regard mollities as an affection allied to, if not identical with, rickets.

The disease which appears best to deserve a separate description under the name of mollities is marked by the following characteristics. Several bones are usually affected at the same time. The portions of bone attacked are uniformly softened throughout. The disease, however, does not in all cases attack either the whole length or the whole thickness of the bone; and, if the specimen be examined at an early period, the outer shell is often found to retain its natural consistence.¹ When the whole bone is affected, it can be readily bent, and resembles, in extreme cases, as Dr. Ormerod² remarks, rather a portion of fatty matter enclosed in a case of periosteum than a bone. If the cancellous tissue (in which the disease appears to originate) be examined, it is found that the cells are enlarged, sometimes to such an extent that the whole bone is expanded, and are filled with a peculiar reddish gelatiniform matter, in which, on microscopical examination, much fat and oil can be discovered, together with blood-discs. Besides these (which are the common products of any degenerative change), certain peculiar nucleolated nuclear bodies have been described by Mr. Dalrymple.³ Instances of bones affected with mollities do, however, occur, in which the amount of fat is not greatly increased. Thus in a specimen in Guy's Hospital Museum (No. 1004⁸⁸), taken from a case reported by Mr. Solly in the 'Med.-Chir. Trans.,' vol. xxvii., it is said that the diseased tissue consisted simply of an organic matrix, with little earthy matter, and containing little fat. Cases like these show that it is impossible to describe mollities as simply

¹ As in Dalrymple's case, referred to below.

² *Brit. Med. Journal*, Sept. 10, 1859.

³ *Dublin Quarterly Journal*, 1840, p. 85; see also *Path. Soc. Trans.* 1846-7, p. 148, and Durham, in *Guy's Hospital Reports*, 3rd ser. vol. x. It is said that in bones affected with mollities, lactic acid and lactates are to be discovered, and that this lactic acid promotes the solution and absorption of the phosphate of lime. The fact, however, appears doubtful. See Drivon, *Arch. gén. de Méd.*, 1867, vol. x. p. 608.

a fatty degeneration. Degeneration of some sort is, however, always present; and, as this advances, it involves the compact walls of the bone, and then the disease becomes for the first time recognisable by the symptoms which will be immediately described. At a later period the whole bone is found to be involved, and becomes a mere bag of soft matter enclosed in the periosteum—which, perhaps, may be somewhat thickened—but it does not appear that any further destruction of the bone itself occurs. It is merely converted into a soft, generally oily, material, which crumbles away on maceration, but which seems capable of resisting absorption for an unlimited period during life.

The symptoms of mollities are sufficiently striking in a well-marked case to attract immediate notice, however obscure may be the real nature of the constitutional affection. The patients are usually women, and repeated pregnancy appears to act as an exciting cause of the disease, and to account for the greater proportion of females.¹

The disease appears to be, in some cases at least, hereditary. Thus, in the history of Dr. Ormerod's patient, referred to above, it is stated that both the son and daughter were subjects of the same affection. Sometimes pain is complained of in the affected bones for some time before the nature of the disease becomes manifest; in other cases, however, the deformity induced by gradual softening of the bones is the first symptom noticed. When this softening has proceeded far enough, the bone gives way gradually, if it has been equally and thoroughly softened, so as to yield, and become merely deformed; but if the softening has been confined to the internal part of the bone, and the thin outer shell has been left solid, and therefore brittle, spontaneous fracture (or, more correctly speaking, fracture from very slight causes) is liable to occur. In extreme cases of mollities the limbs become distorted in the strangest way, so that the thighs have been known to bend till one of the feet touched the head; and, from the softening of the vertebral column and bending of the limbs, the stature is very considerably diminished. The constitutional cachexia is often not very strongly marked, and patients will live in this condition for an indefinite period, bedridden from the weakness of their limbs and the loss of the firm points from and to which the muscles act, but with sufficient mental and constitutional vigour. The cause of death appears generally to be simple exhaustion, or failure of vital powers, like what takes place in extreme old age (in fact, some of these patients do not die till the extreme of life), or sometimes functional disturbance, induced by the altered relations of the viscera, and the pressure to which, from various causes, they are subjected. Not unfrequently, however, the patient does not die of the disease at all, but, having lived under its influence for many years, is carried off by some totally different complaint.

It seems indubitable that in some cases recovery takes place. Out of the 145 cases referred to in Mr. Durham's paper, it is said that 'obvious improvement or cure is stated to have occurred in twenty-two; in eighteen of which, however, the origin of the disease is clearly stated to have been associated with pregnancy or with the puerperal condition; and the pelvic bones alone, or these and the lower part of the spine only, were affected.'² No doubt in such partial cases (and especially when the disease is referable to frequent pregnancy) the prognosis is better; and I am not inclined absolutely to dissent from Mr. Durham's opinion that no case is to be looked

¹ In Mr. Durham's paper reference is made to 145 cases. Of these only 13 were males and 132 females; and of the latter 91 were first affected during pregnancy or very shortly after childbirth. Mr. Durham's figures would lead to the conclusion that the disease usually commences between 25 and 35 years of age. This no doubt depends on the large number of parturient women included in his table. In cases not connected with pregnancy, the disease usually, I believe, begins in advanced life. Dr. Rehn of Frankfort exhibited to the International Medical Congress a well-marked specimen of mollities (clearly not rickets) in a child under two years of age. (Trans. of International Congress, 1881, *Diseases of Children*, p. 59.)

² The most remarkable case of recovery is one of those recorded by Heylard, *Du Rachitis*, &c., pp. 268-74, in which the person affected managed by gradual extension to increase her stature by half a metre, i.e. more than eighteen inches, from what it was at the period of the greatest curvature of the spine. The duration of the case had been at that time about twenty years, and the patient was in good health, though deformed.

on as entirely hopeless so long as 'the walls of the thorax are sufficiently firm for the purposes of respiration, and the bones of the spinal column are prevented from injuring the most vital parts of the cord.'

With these symptoms it is not surprising that this disease should have been claimed as merely a rarer form of several better-known affections of bone, to all of which it bears some resemblance, however little they may seem to bear to each other. Some authors¹ consider mollities to be merely fatty degeneration, or atrophy of bone; others regard it as rickets attacking the adult; while many class it with cancer. Now each of these opinions has a basis of probability, and it is very possible that many of the cases of so-called mollities might with great propriety have been entitled 'atrophy' of the bone. Of this Mr. Curling's case appears to have been a good instance; and the difficulty which some authors have expressed in distinguishing between mollities and fragilitas ossium² appears to have arisen from their having compared together cases in which there was no real difference, and where the name mollities had been given to simple atrophy.

The connection between rickets and mollities appears, at first sight, a very close one, on account of the bending of the bones, and liability to fracture from slight causes, which characterise both. Some patients, also affected with undoubted mollities, have suffered in their youth from rickets.³ Still, if we consider the question attentively, the differences between the two affections far exceed their resemblances. Rickets is an affection of early life, closely allied to scrofula in its causation and in its cure; it is peculiarly amenable to treatment; and under favourable circumstances the constitutional cachexia, which is its essence, readily disappears as the child grows. Mollities hardly ever makes its first appearance till middle life; and, even in those cases where the patient has been rickety, not till long after the cachexia of that disease has subsided; it shows no alliance with scrofula, and is rarely amenable either to the remedies for that disease, or, as far as is known, to any other remedies, but pursues its career steadily, unaffected for good by any medical treatment.

In the latter particular, as in several of its other features, it bears a far stronger resemblance to cancer. In fact, there can be little hesitation in classing some specimens preserved in museums as mollities under the head of diffused cancer; and conversely, in recorded cases of cancer, some of the bones have been found in a state closely resembling, if not identical with, mollities.

Thus in a case of secondary cancer in the spine and other parts, after removal of scirrhus of the breast, related by Mr. Caesar Hawkins,⁴ it is noted that 'the centre of the neck appeared a little sunk forward, as if the upper vertebrae had been depressed in that position; and the anatomy of the affected bone is thus described: 'The body of the fifth cervical vertebra was very irregular on its surface, and was softened throughout, with much enlargement of the cells of the cancelli, which were filled with a sanguineous pulpy fluid; the two adjoining vertebrae showed a lesser degree of the same morbid structure.'

But, allowing that many of the recorded cases of mollities may be referred to simple atrophy, and some of the others to cancer, there can still be no doubt of the existence of an independent disease to which that name is peculiarly appropriate.

In one sense, indeed, all cases of mollities may be said to be cases of atrophy, for the bony matter is greatly diminished, or even quite absorbed; but this proceeds, not from a deficiency of nutrition—in fact, the blood-supply appears at first, at any rate, excessive but, from some error of nutrition, the nature of which is as yet unknown. Some pathologists have tried to connect it with an excess of lactic acid, which, circulating through the bone, produces disintegration of its lime-salts. Others

¹ See Mr. Curling's paper in *Med.-Chir. Trans.* vol. *xx.* p. 356.

² It would be well if the term *fragilitas ossium* were allowed to become obsolete, since it only describes a symptom common to several affections.

³ This was the case with Dr. Ormerod's patient above referred to.

⁴ *Med.-Chir. Trans.* vol. *xxiv.* p. 45. See also a case of cancer of the bones after scirrhus of the breast, described by the author in *Path. Soc. Trans.* vol. *xi.* p. 210, in which some of the ribs were perfectly flexible. In examining a case of well-marked cancer of the pelvis, I have found a condition of the innominate bone bearing an almost equally close resemblance to mollities.

refer it to an excessive demand for lime-salts during pregnancy, in order to form the skeleton of the fetus. Dr. Bence Jones¹ tried to connect it with a supposed loss of a peculiar albuminoid product through the kidneys; but none of these explanations can at present be accepted. The alleged excess of lactic acid is quite unproved. The second explanation is very difficult in itself to accept, and is inconsistent with the fact that the disease occurs in males and in women who have never been pregnant; and subsequent observers have not been able to verify Dr. Bence Jones's observation. Mr. Durham says, however, that in every case known to him the history proves the existence of some influence, or combination of influences, capable of producing great general depression of the nervous system. A case reported in Charcot's lectures, as spontaneous fracture depending on disease of the spinal cord,² bears a great resemblance to some of the published cases of mollities.

The treatment must be directed to supporting the patient's strength, giving good food, attending to the digestion, administering cod-liver oil, quinine and iron, and rectifying as far as possible any malposition of the limbs. The fractures which occur in mollities are not usually insusceptible of union.

The more advanced cases are hardly subjects for treatment, since the disease in the bones and the distortion of the limbs has advanced to an unmanageable extent before the patient is seen; and it would be scarcely desirable, even if it were possible, to protract the course of a painless but inevitable decay.

Malignant tumours. Cancer or Sarcoma.—That most of the soft tumours of bone are highly malignant is unfortunately too true to be for a moment disputed; and, although the nomenclature of these tumours, now in common use, has changed since the general acceptance of the theories of German pathologists about the difference between sarcoma and carcinoma, yet the surgical indications remain the same, and the result of surgical treatment has not hitherto, I fear, greatly improved. I trust, however, that we may hope in the future for some improvement in the ultimate results of operations, from the more careful and extended study of such diseases which has been lately undertaken, and from the increased precision in diagnosis which certainly seems to have been attained.

In the last edition of this work such tumours were divided into cancers or malignant, and myeloid or non-malignant; with the reservation, however, that myeloid tumours sometimes prove malignant, and that, in some cases diagnosed as cancerous, amputation is permanently successful. This classification rested on purely clinical grounds. The new classification professes to be strictly anatomical; but it may be questioned whether it really is so, for it is largely influenced (to say the least) by the theory of Waldeyer, that carcinoma is derived from epithelial structures only—a theory of which no satisfactory anatomical proof has as yet been given. Consequently, as there is assumed³ to be no epithelium in the bones, it follows by an easy process of reasoning that there can be no carcinoma in the bones, and that all soft tumours of bone must be sarcomatous. I must not spend time here on matters of pure speculation. All I need say is that many of the tumours classed as 'round-celled sarcoma' seem to me anatomically indistinguishable from carcinoma, and that they have every clinical character which pertains to cases of 'cancer,' however we define that term; for they sometimes affect the bones in numerous parts simultaneously,⁴ spread rapidly from the bone to the neighbouring soft parts, affect the glands, reappear in the most remote and diverse parts of the body, and destroy life rapidly, whether they are removed or not, and however freely the parts may have been removed.

The soft rapidly-growing tumours of bone are now usually described as—1. myeloid or giant-celled sarcoma; 2. spindle-celled sarcoma; 3. round-celled sarcoma;

¹ *Phil. Trans.* vol. lxxvi. p. 55.

² *New Syd. Soc. Trans.* vol. ii. App. i.

³ I say this is an assumption, since the vascular endothelium may be considered epithelial.

⁴ A beautiful drawing in the Museum of St. George's Hospital, shows separate nodules of what I should call 'soft cancer,' or what others would call 'round-celled sarcoma,' affecting the femur, tibia and patella, and rapidly invading the parts around the bones. Ser. xxi. No. 29.

and, 4. osteoid sarcoma; for which latter term, however, numerous synonyms are in use. A further division is, in each case, into (a) periosteal, and (b) interstitial or central.

The bone in the neighbourhood of the cancerous deposit is often thickened,¹ sometimes to an extent that can be appreciated by external examination.

1. Myeloid tumour usually occupies the joint ends of the long bones,² or springs from the periosteum of the alveolar cavities in the jaws (myeloid epulis); but it is also found in other parts of the osseous system. Its minute anatomy has been described in the essay on TUMOURS. It forms a soft swelling, growing steadily, though not in general so rapidly as the tumours to be presently mentioned, often pulsating,³ seldom spreading to the neighbouring structures or to the lymphatic glands, or infiltrating the medullary canal to any great extent, though to all these statements there are exceptions. The disease is undoubtedly in some cases malignant, i.e. liable to recur after removal, or even after amputation far away from the tumour; while in others recovery after removal is permanent. It is difficult to speak with confidence as to the prospect of recurrence, since it is difficult to obtain full and complete histories of patients who recover after amputation. Dr. Gross calculates that nearly a quarter (22·72 per cent.) of all his cases of myeloid tumour of the long bones have run a malignant course, the recurrence being not only local, or in the stump, but also general, and almost always in the lungs. The same observer believes that the presence of osteoid, or chondroid, formations in a myeloid tumour is of serious import as to its malignancy; that is to say, that the malignancy of a myeloid tumour may be regarded as due, at least in great part, to the presence of such deposits. Myeloid tumours sometimes undergo cystic degeneration ('myelocystic tumours'—Gray⁴), and they usually present in some parts a variable amount of fatty degeneration.

2, 3. Excluding what used to be called 'osteoid cancer,' the other rapidly growing tumours of bone are classified by those who regard all these growths as sarcomata with the 'spindle-celled' and the 'round-celled,' the former being the tumours originally described by Lebert and Paget as 'fibroplastic' or 'recurrent fibroid,' and the latter those which are otherwise (and in many cases better, in my opinion,) denominated 'encephaloid cancer.' Both kinds grow either centrally or subperiosteally. Both are usually malignant, especially the latter, which is regarded as a form of cancer by observers so eminent as Paget, Kindfleisch, and Cornil et Ranvier.⁵

4. The osteoid or calcifying, or partly ossifying malignant tumours, form a class which it is very difficult indeed to separate accurately from the others—if, indeed, there be any radical difference. The chief reason for classifying these tumours by

¹ Paget, *Surg. Path.* vol. ii. p. 362, ed. 1853; *Path. Soc. Trans.* vol. x. p. 249.

² Of seventy recorded examples of myeloid tumour of the long bones, according to Dr. S. W. Gross (*Amer. Journ. of Med. Science*, July and Oct. 1879), only four sprang from the diaphysis. In the long bones the myeloid tumours are generally central, i.e. arising from the medullary tissue.

³ In Dr. Gross's collection of cases above referred to, pulsation was noticed in one-fifth of the myeloid tumours of the long bones.

⁴ *Med.-Chir. Trans.* vol. xxxix

⁵ Dr. Gross divides the round-celled sarcomata into alveolar, lymphadenoid, and granulation-like or hæmatoid, and he gives the following as the differences between the alveolar form and carcinoma. 'The points of distinction are, first, that the cells are intimately connected with the walls of the alveoli or the vessels which form the alveoli; secondly, that, by pencilling, an intercellular substance, like that met with in the lymphadenoid form of tumour, is disclosed, the fibres of which arise from the coarser trabecule which separate the tissue into groups of cells; and, thirdly, that the cells are pretty uniform in shape and size, being round and oval, and about the dimensions of a white blood corpuscle. In carcinoma, the cells are of an epithelial type, loosely heaped in the loculi, without the intervention of intercellular substance, and polymorphous, and vary greatly in size. In other words, in alveolar sarcoma the stroma and cells are intimately interwoven into a single tissue, whereas in carcinoma, the cells and stroma are easily separable into two distinct tissues.' I should observe that these minute microscopical differences are in the highest degree uncertain; and would probably be very differently estimated by equally skilled observers, if unfettered by a previous theory. They certainly appear too weak to prove the permanent foundation of a surgical classification.

themselves as 'osteoid cancer' (a classification which I still think better than the one now in vogue) is the singular circumstance that osteoid or chondroid deposit not unfrequently occurs in the glands and the viscera, and that the disease may recur as a chondroid or osteoid tumour in the viscera, even in cases where there is no local recurrence. Possibly in some cases the formation of bone, or some imperfect resemblance of bone, in these tumours is primary; but in most cases it seems as if the tissue of a soft tumour were invaded by calcification or ossification. The nomenclature of these osteoid tumours must of course depend on that of the soft tumours, of which there are confessedly a variety. If all the malignant tumours of bone are to be called sarcomata, the osteoid must bear the same qualification, absurd as the term seems. But the arrangement is a highly unsatisfactory one, for, except in the anatomical analogy which exists between bone and other connective tissues, these tumours present none of the features which were originally described as characteristic of sarcoma, for they are usually highly malignant, and recur, not locally, but in remote parts; and they invade the lymphatic glands, often at an early period of the disease. But in striking contrast to these very malignant osteoid tumours, which I would still call osteoid 'cancers,' there are others which are only locally malignant—i.e. recurrent—which do not threaten life unless by their pressure, and which in all clinical respects bear the strongest analogy to the 'recurrent fibroid' tumours of Lebert and Paget. Such cases I would class apart from the cancerous tumours by some such term as 'diffused bony' or 'recurrent osteoid' tumours; and they will be found described in the sequel with exostoses.

FIG. 55.—Melanotic Cancer infiltrating the cancellous interior of the shafts of the long bones. From a preparation (Series ii. No. 234) presented to the Museum of St. George's Hospital by Mr. Campbell De Morgan.

showing the uniform infiltration of the cells with melanotic matter. *b*, a transverse section. The cortex of the bone is seen to be quite free in this section, but at other parts a few points of melanotic deposit were met with. The preparation was taken from the body of a woman who had been operated upon for the removal of a melanotic tumour. The disease returned in various parts of the body. The whole skin resembled that of a person who had long taken nitrate of silver, and melanotic matter was found both in the rete mucosum and in the derma. There was also extensive deposit in many of the internal organs.

In exceptional cases deposits are found in the bones secondary to carcinoma elsewhere which can hardly be regarded as otherwise than carcinomatous. Thus, after scirrhus of the breast, I have seen deposits in various bones which could hardly be regarded as otherwise than scirrhus.¹ These deposits were in the form of small irregular lumps, creaking under the knife, emitting a very scanty juice, and presenting under the microscope, besides a good deal of common fibrous tissue, only small nuclear bodies, and those in no very large proportion. They bore a sufficiently close resemblance to scirrhus in other parts to deserve the same name, more especially as they were only another product of the selfsame disease. Epithelial cancer attacks bones usually in the course of a cancerous ulceration of the soft parts which cover them, but scattered instances of its occurrence as a primary disease are on record. Thus in the 'Path. Soc. Transactions,' ix. 358 will be found a description of this disease in the base of the skull. It presented the appearance of a mass of fibroid tissue, the meshes of which were filled with a yellow opaque and thick material, which could be squeezed out in the form of comedones, and consisted of a mass of epithelial scales. But these cases are of too rare occurrence to have much practical import-

¹ *Path. Trans.* xi. 219.

ance; nor in the few scattered cases of colloid disease affecting bones with which I am acquainted is there anything to throw light on the controversy as to the malignant or non-malignant nature of that affection. Melanosis affects bones very rarely, and probably is always a secondary formation; as in the case which has furnished fig. 55.

It seems to result from this that our means of classifying the soft and rapidly growing tumours of bone for any useful surgical purpose are as yet very inadequate. It matters little whether we call a tumour by one name or another, or entertain one or another theory about the tissue in which it originates, so long as we are obliged to confess that we have no resource except immediate amputation, and even then can form no definite idea of the patient's prospects after the operation.

The rules, however, for diagnosing these tumours have undoubtedly acquired some increased precision in this search after classification. In the first place, there may be some difficulty in diagnosing a soft tumour in its early stage from an abscess. The question occurs only, as far as I have seen, in the neighbourhood of a joint; where also the doubt sometimes is, whether the swelling is not due to thickening of the synovial membrane. Generally speaking, however, the soft tumour is limited to one portion of the circumference of the bone, while disease of the synovial membrane would involve the whole circumference, although not necessarily equally prominent over the whole. Further, the chronic thickening of the synovial membrane will have been preceded by a long course of symptoms of disease in the joint, and these symptoms will probably have been more acute at some previous time; while the tumour will have commenced much more recently, at first without any symptoms, and the symptoms will have been more marked as the tumour got larger. Limited abscesses, also, in the thickness of the swelling, are common in the chronic synovial disease, while abscess is a rare complication in the course of a tumour, and then forms external to it and singly.

The following instance of the occurrence of abscess around a rapidly growing tumour will illustrate the difficulty of the diagnosis in such a case. A young woman was admitted into St. George's Hospital under the care of Mr. Caesar Hawkins, complaining of pain near the ankle; no diseased appearance then existed. Soon, however, a soft swelling made its appearance, fluctuation was detected, and an incision behind the internal malleolus gave exit to pus mixed with blood, and exposed a cavity which appeared to be that of an ordinary abscess. After a few days arterial hæmorrhage came on, and soon became uncontrollable. Pulsation also became evident in the swelling. The incision was extended, and several pieces of soft, breaking-down tissue escaped; the finger passed into a mass of fungous matter springing from the os calcis. After amputation the disease was seen to be a soft tumour, about the size of a walnut, connected by a broad base to the calcaneum, and surrounding the posterior tibial vessels. The artery showed a small perforation.

It is seldom, however, that such difficulty is experienced as in this case in forming the diagnosis: and if from the ambiguity of the symptoms, and the thickness or tension of the soft parts over the swelling, doubt is felt as to the presence of a soft solid or a collection of fluid, the introduction of a grooved needle will in most cases decide the question. Usually the lobulated surface of the tumour, and the healthy and uninfamed state of its coverings, suffice to distinguish it from an abscess. The diagnosis between a large deposit from periostitis and the early stage of a malignant tumour depends chiefly on the more limited extent of the tumour, and its more rapid growth; but it is not always easy at first, and thus requires some watching of the case, and the trial of a course of iodide of potassium or mercury. Mr. Morrant Baker's case, referred to on p. 297, will show the possibility, even with all due care, of mistaking the results of common inflammation for those of malignant disease.

In the early stages of soft tumours which pulsate there is often a question as to whether the disease is aneurismal or no; but on this head I think it better to refer to the essay on ANEURISM.

Having settled the diagnosis so far as to determine that the tumour is one of the so-called sarcomata, its position and nature may usually be inferred with tolerable accuracy. With regard to the central or peripheral origin of the growth: a tumour may be regarded as central when its appearance is preceded by a constant aching pain in the spot where it afterwards presents itself; which pain disappears or is

much mitigated as soon as a soft spot in the bone marks the issue of the tumour through its case of bone and periosteum, and this inference is converted into a certainty if the bone suddenly gives way.¹ If the tumour pulsates, it is probably myeloid, though it may be round-celled. If it occurs near an epiphysis, the chances are that it is the former; if in the shaft, probably the latter.

On the other hand, a tumour which grows like a large ferule around the bone, unaccompanied by pulsation, and with no tendency to fracture, and in which the pain is constant, though not usually excessive, may be assumed to be periosteal. If its rate of growth is rapid, and if the glands are infected, or the tumour is covered with large veins, or any other striking feature of malignancy is displayed, it will be of the round-celled (cancerous?) variety—otherwise myeloid or spindle-celled—the former more probably if near the head of the bone.

Osteoid deposit to any great extent is certainly a very unfavourable feature, and especially so if the glands are of bony hardness. There is usually no difficulty in distinguishing between a malignant osteoid or chondroid growth and a common enchondroma, from the slow progress, painlessness, bossy surface, and absence of all serious symptoms in the latter, as contrasted with the distinctly cancerous history and course of the former.

Treatment.—The diagnosis being established, there is no doubt that amputation should be urged in all cases where the long bones are affected, except those in which there are already symptoms of general infection, such as unmistakable deposit in the glands—not merely enlargement which may be due to irritation—constant hacking cough and blood-spitting, enlargement of the liver or any other symptom of visceral deposit. Whether it is in all cases necessary to amputate above the head of the affected bone is doubtful. My own impression is that, provided amputation is done at a level considerably above the affected part,² it is not necessary to remove the whole bone. This is illustrated by a case published by me in the 'British Medical Journal,' July 17, 1880, where the thigh had been amputated eight years previously for a rapidly-growing periosteal tumour of the femur, pronounced to be medullary cancer, and in which there was some enlargement of the inguinal glands on both sides. The patient was (and is) in perfect health. I have met with other similar cases, so that in tumours of the lower end of the femur, I should be disposed to amputate below the hip; though where the tibia, or fibula, or bones of the forearm are the seat of the disease, as there is little extra risk in amputating above the joint, that course is the wiser. The malignant tumours of the humerus which I have met with have been seated so high on the bone as to necessitate amputation at the shoulder; but, if seated low down, I do not see why they should not be treated by amputation through the shaft of the bone.

In the long bones I should earnestly dissuade either the resection of the portion of bone affected or the enucleation of the tumour.³ I had reason to regret having a short time ago, in deference to the wishes of the patient, enucleated a myeloid tumour of the tibia, instead of performing amputation. Abscess spread into the knee joint, and compelled amputation when the patient was too weak to rally from it. But where amputation is impossible, the attempt ought doubtless to be made—the bone being, if possible, freely resected at a distance from the morbid growth. Where this cannot be done, the tumour must be completely enucleated and the bleeding stanchd with the actual cautery, any fresh outgrowths being treated in the same way.

¹ Such spontaneous fractures are not insusceptible of union. Numerous instances are now on record. See the case above referred to, in *Path. Trans.* xi. 219.

² This is undoubtedly necessary, especially if the tumour be central. In a man who was under my care some time ago with a central tumour of this nature presenting in the upper third of the thigh, we found after amputation at the hip, that the medullary tissue was invaded by the growth as high as the neck of the bone.

³ I am aware that cases have occurred in which the shaft of the affected bone has been resected with success for myeloid tumour. (See Gross, *op. cit.* pp. 49, 56). I would not refuse to follow such a course in an otherwise favourable case, if the patient declined amputation, but I should think it dangerous.

Osteo-aneurism.—Ever since the days of Breschet, pulsatile tumours of bone have been described as osteo-aneurism, by which is intended expansions of the wall of the bone by capillaries sufficiently enlarged to pulsate, as such enlarged vessels do in aneurism by anastomosis in the soft parts. There can be no doubt that the great majority at any rate, if not all the cases, described under this head by the older surgeons were myeloid or other soft tumours in which, as we have seen, pulsation is often an early symptom, before the solid matter has attained any large size. Whether all of them are of this nature must be left to the reader's judgment. Many good surgeons think so, including the most recent writer on the subject whom I have met with.¹

The only two cases as far as I am aware which could at all support the view that pulsating tumours of bone occur, which are not sarcomatous or carcinomatous, but mere dilatations of the vessels of the bone, are the following. The first was published by Dr. Mapother in the *Dublin Med. Press*, February 4, 1863, p. 105. In this case there was a pulsating tumour of small size situated on the tibia, accompanied by a distinct thrill and slight bruit; but without any indication of disease in other parts of the osseous system or in the body generally. The diseased tissue was destroyed by two applications of the actual cautery, in doing which its vascular nature was clearly testified by the acute hæmorrhage. No other morbid tissue was exposed by the opening which was made into the tumour; but there was, of course, no opportunity for anatomical examination. The wound healed perfectly, and I am told by Dr. Mapother that the patient remained in good health two and a half years afterwards.

Again, in the *Path. Trans.* vol. xix. 349, is the account by Mr. Bickersteth of a case where he amputated the leg on account of a pulsating tumour of the tibia, which 'felt firm, but was slightly compressible, yielding to deep pressure, and giving a spongy feel to the finger, with an occasional sensation of crackling. The skin was free and sound. No bruit was audible.' An incision was made into the tumour, which exposed a surface having all the appearance of malignant disease, and the leg was amputated under the idea that the tumour was cancerous. On examination of the tibia in front, it was found much expanded at its lower end, where a mere shell of bone remained, bending and crackling under the finger. Behind was a large oval tumour, five inches long by three broad, springing from the posterior and outer side of the expanded tibia, and running upwards from the lower end of that bone into the interosseous space, overlapping the fibula, but not connected with it. It had a distinct wall, and was divided into two parts by the tendons of the tibialis posticus and flexor longus digitorum, which ran in a groove or channel in the tumour, through nearly its whole length. The bulk of the tumour was found to consist of innumerable trabecular spaces; the fibrous bands composing which, as well as the walls of the tumour, were derived from the periosteum of the tibia. These spaces were filled with clotted blood. All parts of the tumour communicated with each other.² There was no admixture of cancerous matter; and the case appeared, both to Mr. Bickersteth and to the committee of the Pathological Society who examined it, to be a perfect example of aneurismal dilatation of the vascular spaces of the bone.

Mr. Bickersteth had the kindness to inform me that he saw the patient many years afterwards perfectly well.

Admitting, therefore, the possibility that in such a case as Dr. Mapother's, the tumour might be found to consist only of vascular tissue, we must also admit that the course he pursued was justifiable; i.e. that in a small pulsatile growth from bone, where no soft solid structure can be discovered, it may be justifiable to remove the growth either by the cautery alone or (perhaps better) by excision combined with the cautery; but I confess that I should always regard amputation as the safer course.

Cancerous ulceration is usually preceded by a known and evident tumour, probably epithelial; but in some cases the malignant deposit may have been entirely interstitial, and in others the patient is not seen until extensive ulceration has destroyed any tumour that might have existed. Such cases occur most usually about the bones of the face; and I have seen death produced where the lower jaw was implicated in a case of this kind, by the extension of the ulceration into the lingual artery. During life some difficulty may be experienced in distinguishing this cancerous affection from the rodent or phagedænic ulceration, spoken of at p. 292; but it is a matter of little practical importance, since amputation or complete excision would be recommended in either case, if the patient's general condition admitted of it. The bones of the face are peculiarly liable to extensive destruction in canceroid ulceration and in lupus, but the chronic course of these affections sufficiently distinguishes them from cancer.

¹ Landi, quoted in *Lond. Med. Record*, Nov. 15, 1877.

² The preparation is preserved in the Museum of the Liverpool School of Medicine.

In the macerated bone, malignant ulceration produces extensive and irregular destruction both of the compact and cancellous tissue, without any trace of the periosteal and other inflammatory deposit that bounds the more healthy forms of ulceration (see fig. 56).

Non-malignant tumours.—The tumours which may, without hesitation, be regarded as innocent are those which present a complete resemblance (homology) to the natural tissues of bone; i.e. the cartilage, the osseous tissue, the fibrous membranes, and the spaces or cancelli.¹ Hence they are described as cartilaginous (enchondromata), bony (exostoses), fibrous, fibroid or fibro-cystic, and cystic tumours, to which entozo must be added. The sarcomatous tumours present, as we have seen, a dubious analogy to the natural tissues, and their claim to the title non-malignant is still more dubious.

FIG 56.—Malignant Ulceration of Bone. (Museum of the Royal College of Surgeons. No. 640.)

FIG 57.—The Humerus in a case of diffused Cartilaginous Tumour (Museum of St George's Hospital Series ii. No 183)

Enchondroma.—Cartilaginous and bony tumours can hardly be treated of separately, for although the well marked specimens of either class present little similarity at first sight, some of each are so intimately related, that the two could not without confusion be made the subjects of separate sections.

Cartilaginous tumours, or enchondromata, as they are called, have been already described in the essay on Tumours (vol. i. p. 264), so that it now only remains to speak of them as they affect the bones.

These formations may be divided, for surgical purposes, into two classes: the circumscribed and the diffused. The former as a rule do, and the latter do not

¹ We have discussed above the question of the reality of the growths described as osteosarcoma. If they occur, they are the homologues of the vessels, or rather outgrowths from them.

show a tendency to ossify throughout their whole extent; although even in the diffused enchondromata the part of the bone from which they spring is often occupied by a considerable osseous deposit, while the bulk of the tumour remains unossified. The diffused enchondromata usually grow as extensive infiltrations into the tissue of the bone and periosteum, and in the course of time spread slowly over the surface of the bone (retaining for the most part their covering of periosteum), and fill all the spaces or cavities in relation with the bone. Such was the case in the instance shown in fig. 57, where the whole medullary canal of the shaft of the humerus is occupied for a considerable extent by porous bone forming the base of a cartilaginous tumour, which surrounded the bone, and had been growing for a long period without much inconvenience to the patient. It is difficult to determine their precise origin, and thus to make sure whether they are new formations, in a strict sense, or out-growths. The former opinion seems more generally probable, but it is possible that some of them originate in early life as out-growths from the epiphyseal cartilage. These non ossifying cartilaginous tumours, or pure enchondromata, are little amenable to surgical treatment, unless in a part favourable for amputation.

FIG 58.—Cystic Enchondroma. (Museum of the Royal College of Surgeons. No. 203A)

They have been supposed to present some analogy to malignant diseases, to which, indeed, their extensive diffusion and steady irresistible progress do offer a resemblance. They differ, however from the true cancers, at any rate—in one feature, which is quite characteristic, viz that, however extensive their diffusion, they affect the surrounding parts only by pressure or absorption, not by contamination. This is their most distinctive feature, but it is not so useful in diagnosis (since it is less easily appreciated during life) as their rate of growth, which is usually slow. To this rule there are, however, rather frequent exceptions, of which three remarkable instances are related by Sir J. Paget,¹ in one of which the rapid growth of the tumour led to the erroneous diagnosis of malignancy, and so deprived the patient of the chance of recovery which amputation would have given him. Remembering these and similar cases, we must not be too confident in inferring malignancy in the case of a tumour of bone from the single fact of rapidity of growth, although that is, doubtless, a most suspicious and unfavourable symptom. In many cases these large cartilaginous tumours remain stationary for a long period; and this should be taken into consideration when consulting on the propriety of amputation.

¹ *Lectures on Surg. Path.* vol. II. p. 181, ed 1853.

The structure of these tumours varies; usually they are quite solid; in other cases cysts, filled with fluid, are found in them, as in the beautiful specimen from which fig. 58 was taken. They sometimes consist exclusively of cartilage; but more commonly fibrous tissue is to be found, in sparing quantity, in some parts of them. The microscopical appearances will be found described in the essay above referred to.

The circumscribed cartilaginous tumours are, however, much more frequently met with, and are, therefore, more important in practical surgery. They spring almost exclusively from the long bones, the phalanges of the fingers and toes being their most frequent seat. A small enchondroma is comparatively often met with, springing from the end of the last phalanx of the great toe, raising the nail up, and giving a good deal of pain in wearing the boot. It should be cut away from the bone, and usually will not return; should it do so, the phalanx must be removed. In the hand and foot enchondromata are often found in great numbers at the same time; and the appearance thus presented is very characteristic, and is not, as far as I know, imitated by tumours of any other kind.

The fingers are studded over with bosses or knobs, looking something like the dry gnarled branches of an old tree. Of this form of disease the annexed is a good illustration. This affection is seen generally about the age of puberty. It is, of course, quite incurable, except by amputation; but that measure should never be resorted to in any disease of the hand without evident necessity. In the foot less scruple need be entertained, since the foot, deprived of its anterior portion, is still a very useful member; and there would be no necessity, even in a very advanced case, for going further than Lisfranc's or Chopart's operation. I have never seen a case where anything more was required than to remove one or two toes. In the hands these multiple enchondromata, if left alone, grow generally very slowly, and sometimes not at all. Cases are, however, on record where they seem to have increased slowly during the whole period of life, and to have attained at length a truly extraordinary development. Of this the specimen figured by Müller¹ is an excellent instance; and a very similar case has been described and figured by the writer,² where, however, the carti-

laginous structure was less distinct. Such tumours usually originate in the interior of a bone, expanding its walls into a thin bony cyst or shell, which is liable to give way at different parts, and firm pressure will then elicit a feeling of crepitation (see fig. 60, on p. 325). These multiple enchondromata, like the diffused cartilaginous tumours just described, seem to show little tendency to ossify in the strict sense of the term; but they undergo, when very old, a process of calcareous degeneration, which, added to their general increase in size, produces ulceration of the skin over them; and so a condition is brought about not unlike that of a mass of enormous chalkstones exposed. More rarely the tumours spring from the surface of the bones.³

FIG. 59.—Model of a Hand affected with numerous Enchondromata. (From the Museum of St. George's Hospital.)

¹ *Ueber den feinem Bau und die Formen der krankhaften Geschwülste*. Berlin, 1838, tab. iv. fig. 1.

² *Path. Soc. Trans.* vol. ix. p. 382. The specimen is in the Museum of St. George's Hospital.

³ With regard to the ordinary seat of cartilaginous tumours of bone, Dr. Pirrie makes the following observations, which I believe to be generally true: 'I have now seen in my own experience nine specimens of cartilaginous tumours near the ends of long bones, and they have all been situated between the walls of the bone and the periosteum, and in no instance extended to the cartilage of incrustation at the end of the bone. I have met with fifteen

Circumscribed and solitary enchondromata usually grow from the surface of a bone, and most of them show a strong tendency to ossify, the process commencing generally at the base. Hence the surgical considerations applicable to them are identical with those which apply to exostosis. When a circumscribed enchondroma grows in the interior of a bone, as in fig. 60, it can be readily enucleated, and when a small cartilaginous tumour springs (as it often does) from the end of the last phalanx, usually of the great toe, its removal is very easy, and is always, as far as I have seen, permanently successful.

Diagnosis.—The diagnosis of innocent tumours from each other is uncertain and obscure in all parts of the body, and perhaps more so when they are connected with the bones, on account of the generally deep position of the latter. If, however, a tumour presenting the general characters of innocence can be clearly made out to be springing from bone, the chances are very great in favour of its being an enchondroma or an exostosis. If very large, it can hardly be the latter without displaying characteristic hardness. Fibrous and fibroid tumours may be found of large size; still almost all large non-malignant tumours of bone are cartilaginous. Most, also, of the smaller tumours, which do not possess the hardness of exostosis, will be found to be cartilaginous. Such tumours usually possess a certain amount of resilience, and often appear obscurely movable on the bone. This sensation, however, is often deceptive, and due, apparently, to the motion of the soft parts upon the tumour; it has been noticed in tumours the base of which has been found to be completely ossified, and a slight amount of apparent movement is therefore no conclusive reason for denying the connection of a tumour with the bone. Another thing which ought to be taken into account in diagnosis is, that the cartilaginous, equally with the osseous, tumours may have a bursa over them. This will not often be an obstacle in the way of making out an exostosis, since the hardness of the latter is transmitted through the fluid, but may sometimes cause doubt about the nature of an enchondroma. The nodulated surface of enchondroma, though characteristic to a certain extent, is far from distinctive of the disease; the same property may belong to colloid disease, fibrous tumour, and other swellings; in fact, the only sensation which affords a reasonable ground for pronouncing a tumour cartilaginous is resilience combined with solidity; and this for deep-seated tumours is often deceptive, and in the many enchondromata enclosed in shells of bone is, of course, absent. On the whole, therefore, an enchondroma is best known by its being an innocent, and not osseous, tumour; elastic when firmly pressed, generally growing slowly, and not affecting the skin. When the phalanges are the seat of the disease, the diagnosis is much more nearly certain.

Exostosis.—The transition from cartilaginous to bony tumours is a natural one, since so many of the former are merely the first stage of growth of the latter. The term 'exostosis' is not a very easy one to define. It ought to be used only to signify an innocent tumour, or limited outgrowth, formed exclusively of bone, and not the result of inflammatory action; but, on the one hand, the products of inflammation secreted by the periosteum often assume the form of a limited outgrowth or tumour: while, on the other, many complex malignant tumours possess a bony framework, and, after maceration, bear a great resemblance to exostosis. In the latter case the distinction, though occasionally difficult after the bone has been macerated, is easy during life; so that the mere fact that a malignant tumour possesses a more or less perfect bony framework is of little moment in a practical point of view. Most of the growths which fall under the category of 'periosteal examples in metacarpal bones, and they all originated within the bone, and caused more or less of expansion of the walls and their conversion into a thin crust or shell around the tumour, in various instances at parts completely absorbed. I have seen and carefully examined seven examples of the same kind of growth in the middle of the long bones, and they were all placed within the canal and around the wall of the bone. Judging from my own comparatively limited experience, I would conclude that the favourite site of the first class is around the bone; of the second within it: and of the third, both within and around it.—On *Acupressure*, p. 107.

exostosis¹ are extensive inflammatory deposits beneath the periosteum, which neither require nor admit of surgical treatment. Whether limited, pedunculated, and therefore removable, tumours ever occur as a consequence of inflammation is as yet doubtful; but we may admit that it is, at least, possible.

The great majority, however, of those bony tumours which are called, in surgical language, exostoses, originate by an out-growth or limited hypertrophy of analogous parts, just as fatty, fibrous, and other innocent tumours do, quite independent of any inflammatory symptoms. Many authors, especially the French surgeons, speak of 'bullous exostoses,' meaning apparently by this term those shells of bone which sometimes are formed by the development of a tumour (generally cartilaginous) in the centre of a shaft. Such a case was the one from which fig. 60 is taken. Another kind of exostosis is that which proceeds from the ossification of tendons, or from the occurrence in man of processes of bone natural to the lower animals. Both of these belong rather to the class of museum curiosities than of subjects of practical interest.

Excluding these rarer varieties, the cases of circumscribed exostosis which surgeons have to treat are divided into two classes—the cancellous, and the ivory; the former being a reproduction of the tissue of the interior, as the latter is of the hard exterior of the bone. They will be found described in the essay on Tumours (vol. i. p. 266).

FIG. 60. — Bullous Exostosis on the Phalanx of a finger; probably a shell of bone expanded around a cartilaginous tumour. (From a preparation in St. George's Hospital Museum, Series ii. No. 151.)

FIG. 61. — Ivory Exostosis which was trephined unsuccessfully, on account of its great hardness. Exfoliation was afterwards produced by the long-continued application of caustics, chiefly nitric acid. (From the Museum of St. George's Hospital, Series ii. No. 189.)

Treatment.—The slow rate at which exostoses progress, and the ease with which these soft parts accommodate themselves to the gradual advance of the tumour, render it frequently unnecessary to meddle with them; and it is always right to defer the operation until it is clearly seen to be necessary, since there is always some risk in operating on any deep-seated tumour, and still more in laying open the cancelli of bone, as must be done in dividing the neck of an exostosis. When the exostosis is of the ivory variety, and situated on the cranium, the operation is much more dangerous. Here, indeed, it not unfrequently happens that the tumour is so hard as to resist all the tools which can be brought to bear upon it, so that it is physically impossible to remove it.

A striking example of this occurred in a case which has furnished a preparation to the Museum of St. George's Hospital. A man, suffering from a small ivory exostosis in the frontal region, fell under the care of the late Mr. Keate, one of the boldest and most skilful operators of his day, who, perseveringly, but vainly, endeavoured, by the use of trephine, saw, chisel, and mallet, during the space of nearly two hours, to cut off the little lump of hard bone. The patient was fortunate enough to recover from this proceeding; and Mr. Keate, convinced of the uselessness of further operation, determined to attempt the extirpation of the tumour by the free application of potassa fusa and nitric acid to its exposed base. This was successful.

¹ See Gerdy, *Maladies des Organes des Mouvements*, p. 272; Fano's edition of Vidal de Cassiz, *Pathologie externe*, vol. ii. p. 261.

The caustics, in the course of years, ate their way through the base of the tumour, which dropped off. The tumour figured in the accompanying illustration (fig. 61) still shows the deep groove worked into it by the trephine at the time of the operation.

It would rash to say that such operations are unjustifiable, since exostosis in the neighbourhood of the orbit may grow into that cavity, or into the cranium, and cause death, or some horrible deformity almost worse than death, by displacement of the eyes, or the bones of the face;¹ but the risks of operating on these small exostoses on the cranium should be maturely weighed. Some tumours, however, which present on the surface the character of the true ivory exostosis, may turn out on section to be hard only on the exterior, and to consist of a soft diploic tissue internally. This is the case usually, if not solely, when the bone from which the tumour springs resembles the composition of the vault of the skull—that is to say, consists of diploë covered by a thin table of compact tissue. In bones of which the ~~bone~~ is more dense, such as the lower jaw, it is much more probable that the whole thickness of the tumour will be of compact structure. Another circumstance which renders the prospect of operations on large exostoses, whether on the skull or other parts, rather more promising than would appear at first sight, is that the tumour when exposed is sometimes found to be connected to the surface of the bone by a very narrow neck, from which it can be easily broken or cut off.² It is, however, only rarely that either the surgeon or the patient will make up his mind to the dangerous and doubtful experiment of an operation on an ivory exostosis, especially of the cranium; whereas operations on the more common forms of exostoses which spring from the shafts of the long bones, and present the cancellous, or mixed cartilaginous structure, are of daily occurrence. Their most common situation, after the phalanges, is near the knee, springing from the inner surface of the femur, a little above the condyle. Another very common situation is beneath the deltoid muscle.

The removal of such an exostosis is, in most cases, easy, since the base is not generally very broad, nor the ossification very compact. Some are even so soft as to be divisible with a strong scalpel. A few again are not united to the shaft by bony matter, but by ligamentous union; usually as the result of fracture of the base of the exostosis, sometimes possibly from partial ossification of an enchondroma, and even perhaps from the formation of bony tumour in the soft parts near the bone. This condition is highly favourable for operation, not merely because the tumour can be more easily excised, but also because the vascular spaces in the bone will not be laid open in the operation.

In other cases the tumour is broader, and more firmly ossified at its base than in any other part, and these are the least favourable cases for operation, since the division of so large a mass of bone requires great and prolonged violence, peculiarly likely to be followed by the complications above enumerated. But the operation is necessary when the tumour is growing, and is threatening the functions of important parts; and in such cases the operator must be prepared for the difficulties which he may have to encounter, and should have a sufficient supply of instruments of adequate strength at hand, such as stout bone-nippers, a chain-saw, other saws of various shapes, chisels, and mallet. In all cases the base of the tumour should be clearly exposed, and separated with care from the parts around, which may require to be held back with retractors. The separation should be commenced from the side where any danger is to be apprehended (*e.g.* in consequence of the proximity of a vessel or joint), in order to avoid implicating any important part; and then any amount of force necessary must be carefully but firmly applied, the bone being steadied by assistants.³ The antiseptic method is now almost universally employed.

¹ Some remarkable specimens are in the Museums of St. Bartholomew's Hospital and of the College of Surgeons. Exostoses of the orbit are not always of this dense quality. See a case in *Path. Soc. Trans.* vol. xi. p. 204, where the tumour was soft, and easily removed.

² A most interesting case of a tumour of this kind, growing from the cranium, is reported in the *Path. Soc. Trans.* for 1850, p. 149, with a drawing, and has been commented on by Mr. Prescott Hewett, in his Lectures on 'Diseases of the Head.'

³ It may not, perhaps, be out of place to remark, that in case of an exostosis situated near

Some surgeons, and especially the late Mr. Maunder,¹ have recommended the subcutaneous section of the neck of an exostosis, or its fracture without any incision. The bony mass is to be prevented from reuniting to the surface of the bone by reiterated passive motion. I have tried this plan once or twice, and seen it tried by others, but never with success, as the tumour always reunited to the bone. Still in situations where the removal of the tumour would be peculiarly hazardous, and where its base is narrow, the plan deserves a trial.

The 'bullous exostosis,' or central enchondroma contained in a bony cyst, usually requires amputation of the phalanx upon which it is seated. It may, indeed, be sometimes possible to enucleate the growth, and I have seen this done with success; but as a general rule it is hardly worth while to attempt it; since, if the disease be seated in the hand, the necessary disturbance of the tendons would probably render the finger useless; and if in the foot, the certainty of a speedy and complete recovery would outweigh the advantage of preserving a portion of one of the toes.

Diffused bony, or innocent osteoid, tumour.— Besides these forms of limited exostoses, a diffused bony tumour is occasionally met with, in which the whole thickness of the bone for some distance is converted into a lobulated mass of spongy bone, which, in a section of such a tumour that I had the opportunity of examining microscopically, presented the usual structure of bone, but with smaller cavities, and an increased deposit of the granular base.

The specimen (in the Museum of St. George's Hospital, series ii. No. 185) is larger than a man's fist, and involves one side of the lower jaw, from the condyle to near the symphysis. Its innocent nature is clearly proved by the fact that it had been growing for five years without any detriment to the general health, and had been partially removed on a previous occasion without any ill consequences from cutting into the interior of the tumour. On the patient coming under the care of Mr. Latun, the tumour was completely excised, and with success, as the man was seen in perfect health several years afterwards.²

Another still more remarkable case is illustrated by a series of three preparations in the Museum of the College of Surgeons. The history is so interesting that a condensed report of it must be introduced. The thigh was originally amputated on account of a hard and heavy dry osseous substance, surrounding the ends of the femur and tibia, projecting into the knee-joint, extending far up the thigh, and implicating the popliteal artery, vein, and nerve, so as to cause oedema and severe pain (Prep. No. 3244 shown in the accompanying figure). The patient remained well for five years; then another osteoid tumour formed on the stump of the femur, accompanied with severe pain. Amputation was performed higher up. The tumour appeared to grow not from the bone itself so much as from the periosteum, and enclosed the femoral artery (Prep. No. 3245). There was again an interval of health for two years; then a fresh tumour

FIG. 62. Diffused bony Tumour of the Femur and Tibia: the popliteal vessels and nerve are seen surrounded by the bony growth, the veins varicose from the pressure. The tumour overlaps the fibula, which, however, is not affected. (Museum of the Royal College of Surgeons, No. 3244.)

the knee-joint, there is the more danger of opening the joint, since the presence of the tumour has probably caused numerous attacks of synovitis, which have left the pouch of synovial membrane extending up the thigh permanently enlarged.

¹ Mr. Maunder published (in *Clin. Trans.* vol. xi. p. 59) two cases in which the exostosis was twisted off with strong pliers without any incision. In one the tumour reunited, in the other not. I have tried both this plan and the subcutaneous section of the neck of the tumour.

² *Path. Soc. Trans.* 1848-9, p. 95.

formed about the stump, continued to increase upwards, out of reach of operation, and finally killed him, from inflammation and sloughing of its soft coverings, *twenty-five years* after the first appearance of the disease. He had been in good general health during the whole time (Prep. No. 3245, A).¹

This history presents a remarkable analogy to that of the recurrent fibroid, or fibro-plastic, tumours of soft parts. There are the same leading features, viz. the local malignity of the disease combined with innocence constitutionally, its imperfect imitation of the tissues in which it grows, its constant recurrence near the site of an operation, and, finally, the mode of death—from exhaustion and sloughing after repeated operations, not from infection of the system. The modern custom of classifying such partially or locally malignant tumours as ‘sarcoma’ along with some of the most malignant diseases of which surgeons have any experience cannot in my opinion be long maintained. I would refer to what I have said on a previous page (317).

Cysts in bone are of two kinds; viz. serous and sanguineous. The serous, or mucous, cysts which occur in the jaws as a consequence of irregularity of the growth, or position, of the teeth will be found treated in a subsequent essay. In such cases the formation of a cyst containing clear fluid is susceptible of an intelligible explanation; but it is difficult to see how simple serous cysts can be developed in other bones, and probably the few cases which are to be found in books rest upon erroneous diagnosis.² But cavities containing clear fluid are formed in bones by the growth of hydatids in their interior; and if simple cysts do occur, they would be indistinguishable from hydatid cysts before operation, and would require the same treatment.

Blood-cysts are not of common occurrence, nor is it usually easy to determine their pathological nature. Many of the cases reported under this title appear to have been examples of malignant tumour, in which a cyst has been developed, much exceeding in relative size the solid portion of the growth.³

Blood-cysts could only be distinguished from serous or hydatid cysts by puncture. In the great majority of cases they would require complete removal, by amputation if necessary. If the surgeon can satisfy himself of the absence of all soft solid matter around the cyst, he may in rare cases be justified in endeavouring to procure its obliteration by laying it open and stuffing it with lint; but it must be borne in mind that such measures can only do harm if there be anything of a malignant taint about the disease.⁴

Fibrous and fibro-cystic tumour.—Perfect fibrous tumours appear as out-growths from the periosteum; and the most familiar examples of them are the fibrous polypus of the nose, which is treated of in the essay on DISEASES OF THE NOSE, and epulis, which will be found treated of among the DISEASES CONNECTED WITH THE TEETH. In other situations, fibrous tumour could hardly be distinguished from enchondroma before removal, and the diagnosis, even if it could be made, would be quite unimportant. We need not, therefore, give examples of the disease occurring in other parts of the body. Scattered specimens will be found in most of our large museums, and in many of them ossification will be found to have made some progress. In some of these cases the innocent nature of the disease is proved by the history; in others it is an inference from the structure of the tumour. Cal-

¹ Another, and very similar, case may be found in Paget's *Lectures on Surgical Pathology*, vol. ii. p. 506, ed. 1853.

² Mr. Stanley (*op. cit.* p. 194) denies the formation of simple cysts in any other bones than those of the jaw.

³ See a case reported by Mr. Liston, under the name of ‘ossified aneurism of the sub-scapular artery,’ *Ed. Med. and Surg. Journ.* vol. xvi. pp. 60, 215. See also Travers's case, *Med. Chir. Trans.* vol. xxi.; and Stanley's, in his *Diseases of Bones*, p. 187.

⁴ In Nélaton's *Path. Chir.* vol. ii. p. 48, will be found a striking representation of a large multilocular cystic tumour developed in the femur, and containing bloody fluid. Unfortunately there is no history of this case.

cification occurs in these as in other fibrous tumours (St. George's Hospital Museum, ser. ii. No. 152).

Fibro-cystic tumour of bone is a disease which is little known, and may therefore possibly be of very rare occurrence. It is, however, also possible that this apparent rarity may be due to the fact that most of the examples of this disease have been confounded with malignant tumours. A very interesting account of a growth of this sort connected with the femur, in which the limb was removed at the hip-joint by Mr. J. Adams, will be found in 'Path. Soc. Trans.' vol. v. p. 254, and, appended to the account of this case, a report by Mr. Prescott Hewett on three similar cases, in all of which the femur was the seat of the disease, and in all of which the patient recovered after amputation, and remained well for many years afterwards. There is therefore the strongest reason to believe that the disease was not cancerous. It commenced, in each of the four instances alluded to, in the cancellous tissue of the bone, making its way outwards, infiltrating the shaft, and causing spontaneous fracture; so far, therefore, exactly resembling cancer. It gave the sensation of an elastic substance, with fluid here and there in cavities. There seems to have been no diagnostic mark between it and cancer during life, except the negative indications to be derived from the absence of glandular or constitutional contamination during a somewhat long disease, the duration of the affection being, in the two cases in which that point was noted, three and four years respectively. On examination after removal, the innocent nature of the disease was inferred from the large quantity of firm fibrous tissue of which nearly the whole solid portion of the tumour was formed, the presence only of such cellular elements as are found in growing fibrous structures, and the absence of cancer-juice, or any other indication of a tendency to disintegration in the tumour, or infiltration of neighbouring tissues. Such tumours would now probably be included under the miscellaneous designation of sarcoma.

Entozoa in bone.—A very few words must suffice for the description of the cases of entozoa in the interior of bone. The entozoon appears to have been the ordinary echinococcus in all cases except one quoted by Mr. Stanley, in which the cysticercus telæ cellulose is said to have been found in the interior of one of the phalanges. The subject is of no very great practical importance, since it is seldom possible to diagnose the nature of the affection previous to operation. The cases are so rare, that in the great work of Rokitsansky¹ only eight are referred to, as the total number which he supposes to have been then observed. A search, however, through the various pathological collections would probably discover many more than these.² It is noticed by Rokitsansky,³ that the disease appears often to be directly induced by some injury; but it is difficult to believe that this can be otherwise than accidental. The disease runs a protracted course, and if the shaft of a long bone be the part affected, fracture, spontaneous or accidental, is very probably the first thing noticed. The fracture, in all probability, does not unite; and it has sometimes happened that in an operation, undertaken for the purpose of resecting the ends of the fracture, the hydatid cavity has been exposed and the globular accephalocysts discharged.⁴ Amputation is then indicated in ordinary cases; but one is on record, in which the hydatids were scooped out of the cavity of the cyst, which then filled up and a complete cure was obtained.⁵ In other cases, the seat of the disease is in a flat bone, as the skull,⁶ or ilium,⁷ or in the expanded head of one or more of the long bones.⁸ These cases are quite within the reach of cure when

¹ *Syd. Soc. Trans.* vol. iii. p. 184.

² The Museums of Guy's and St. Thomas's Hospitals contain at least five specimens.

their nature is discovered; and in some rare instances, as in Mr. Coulson's and Mr. Stanley's cases, the discharge of hydatids through a spontaneous opening or a puncture, enables the surgeon to determine the nature of the disease beforehand. Failing this, the symptoms are precisely those of any other cystic tumour of the bone.

The treatment appears to be usually successful. The cyst is to be freely laid open, with the trephine or bone-nippers if necessary; all the hydatids removed, and some caustic¹ applied to the whole interior of the cyst. In most of the recorded cases this has been sufficient; but in Mr. Coulson's case the cure was not completed until after the separation of a small piece of bone from the floor of the cavity, which on examination was found thickly studded on both its surfaces with a great number of minute hydatids.

HYPERTROPHY AND ATROPHY OF BONE.

The condition of bone usually known by the name of hypertrophy is very generally the consequence of chronic osteitis, and would perhaps be more conveniently

FIG. 63. — Hypertrophy of the Cranium. (Museum of the Royal College of Surgeons, No. 2885.)

designated by some name expressive of its inflammatory origin. Thus, most of the specimens of 'hypertrophied cranium' seen in our museums will be found, if the history be known, to be taken from cases of injury, or to be connected with syphilis or scrofula. The cases also of elongation and thickening of the bones of the leg, related by Mr. Stanley² under the head of 'hypertrophy,' appear all of them to fall more naturally under consideration with the sequelæ of inflammation, which have been described above. It appears that this thickening may go on for an indefinite period after the cessation of any symptoms, and that the enlargement of bulk which follows from it is permanent. It is true that in many of the cases of thickening, whether of the skull or of the long bones, which are preserved in pathological collections, no history of injury or inflammatory affection has been obtained; but the exact resemblance of the specimens to those in which such a history does exist,

Museum, c. 253-4, hydatids were found simultaneously in the lower end of the femur and contiguous head of the tibia. Other cases are noticed in the bodies of the vertebræ. Dupuytren, *loc. cit.* Guy's Hospital Museum, No. 1029^o.

¹ Nitrate of silver, lint impregnated with a saturated solution of sulphate of copper ('blue lint,' as it is called at St. George's Hospital), caustic potash, and the actual cautery, have been used.

² *Op. cit.* p. 5.

leaves no doubt that most of them are specimens of chronic inflammation. To this inflammatory category of hypertrophy also belong the cases of *ostitis deformans* (Paget) referred to on page 281.¹ Cases do, however, occur, though so rarely as to be rather matters of curiosity than of practical interest, in which a bone (the skull for the most part) has gone on increasing in size without any symptoms except those produced by its increase in bulk. Such as the well-known instance related by Mr. Prescott Hewett, in his lectures at the Royal College of Surgeons, in which a man's skull continued to increase in size from year to year, with no symptoms whatever, so that he was only aware of the fact from the increasing size of his hat (fig. 63). The disease, however, in this case was clearly traced to an injury. As no symptoms can be attached to such cases, no treatment is known to have any influence upon them. In the absence of any constitutional affection, the persevering use of counter-irritation, by iodine or blistering, would appear to hold out most hopes of checking the growth.

Atrophy of bone is a more frequent and a more important disease than the opposite condition of hypertrophy. Inflammation, fatty degeneration, disease, and injury are frequent causes of atrophy; and there is also a simple atrophy, in which the composition of the bone is unaltered, and in which no obvious cause is present (unless it may be the general failure of nutrition in advanced life), and where the amount of bony tissue becomes gradually less and less, until the bone is no longer strong enough to resist slight violence.² As a consequence of senile change, or fatty degeneration, atrophy is one of the most common causes of spontaneous fracture. It may also occur in any bone, to some extent, as a consequence of confinement during a lingering disease.³ Brodie says,⁴ 'All bones in a state of inaction lose a great part of their phosphate of lime. After compound fracture, when the patient has been long confined, the bones in some instances become as soft as a scrofulous bone, so that you may cut them with a knife.' The cases which are spoken of under the name of '*fragilitas ossium*' appear to belong for the most part to the class of fatty or senile atrophy. Injury sustained in fracture is also a frequent cause of atrophy. Mr. Curling⁵ believes that the cause of atrophy after fracture may often, if not always, be found in injury to the medullary artery. Even allowing, however, that this explanation is plausible in some cases, there are others where it cannot apply. Such are cases of atrophy of both fragments, or of the bone in the neighbourhood of the fragments, while the latter are not so much atrophied.⁶ Atrophy from inflammation is a condition illustrated by many morbid preparations, though it does not attract much attention in practice. It is merely the persistence of that degenerative change which leads to inflammatory softening; and probably many of the cases of atrophy after fracture should be referred to this head. Extreme instances of this atrophy after fracture are referred to on page 293.

Connected with atrophy is the suspension of growth, occasionally, though rarely met with, in which the epiphyses remain separate from the shaft of the bone; and it seems probable that injury to the epiphysial cartilage, in separations of the epiphysis, may occasionally give rise to shortening of the bone from suspension of growth between the shaft and epiphysis.⁷

Atrophy of bone is an affection which does not appear to be marked by any

¹ In the very interesting paper to which reference was made under the head of *Mollities Ossium* (p. 313), Mr. Darlman divides cases of hypertrophy of the cranial bones into two classes, those which are light, crumbly, and porous, somewhat resembling mortar, which he calls porous hyperostosis or osteoporosis, and those which are hard, dense and heavy, which he denominates sclerotic hyperostosis. The former he believes to be instances of cured or arrested mollities, the latter the sequelæ of rickets. I must refer the reader to the original.

⁵ *Med.-Chir. Trans.* vol. xx.

⁶ See a preparation in St. Thomas's Hospital Museum, Series c, No. 2. Here the atrophy is most marked in the upper part of the shaft; and the fragments included between the fractures (which were triple) are thicker than either of the portions of the shaft.

⁷ Holmes, *Surgical Treatment of Diseases of Infancy and Childhood*, 2nd ed. p. 238.

peculiar symptoms, or to admit of any special treatment. After injury to any part, the restoration of moderate functional activity as soon as it can prudently be recommended, the avoidance of any cause of pressure on the main vessels or those of the surface, and the choice of a suitable posture, with attention to the general health and nutrition, are the objects of a judicious treatment, irrespective of the condition of any particular part; and these measures are all that could be suggested to avert atrophy of the bone, even if it were known to be impending.

Spontaneous fracture has been mentioned repeatedly in the previous pages, in connection with several morbid states, which may be thus enumerated in the order of their presumed frequency as causes of fracture: viz. senile atrophy, malignant disease, tumours of other kinds, including hydatids; disorders of nutrition depending on disease of the spinal cord;¹ the ulceration which accompanies necrosis, and, lastly, other kinds of ulceration. But besides these, cases of spontaneous fracture occur without known cause; sometimes in making a violent muscular effort, as in throwing a stone, or striking a blow; at other times in the most ordinary action, as in turning in bed, quiet walking, &c. Those which are caused by violent muscular efforts too nearly resemble the ordinary cases of fracture (particularly fractures of the patella) to call for any remark here; and the treatment of the fracture in the cases which occur during the progress of known disease is a matter usually of subordinate importance, and has been already sufficiently discussed in treating of the disease. I would merely add, that when the long bones are perforated by ulceration occurring around a sequestrum, the question of amputating the limb, or attempting to save it, will demand much care, and that, as a general rule, amputation will not be required in the upper extremity, nor should it be performed in the spontaneous fracture which rather frequently follows acute necrosis in children, unless the general health is evidently giving way; but in other cases of necrosis of the bones of the lower limb, and in almost all cases of ulceration not due to the separation of a large sequestrum, amputation as a general rule is indicated. When fracture occurs during the ordinary muscular exertions of everyday life,² and in persons not known to labour under any disease, various remote causes have been imagined, but none have been proved to be really efficient. The one most commonly admitted is syphilis; but, not to dwell on the fact that the accident has occurred in many persons in whom the strongest reason existed for believing that no such taint was present, all that we know of the action of syphilis on the bones tends to show that (apart from ulceration and the separation of necrosed portions) it renders them not more but less brittle. The practical point of chief interest connected with such cases is, that there is no reason to despair of union, and that they should be treated in the ordinary way, with perhaps more than the ordinary care to avoid constriction of the soft parts.

Wounds of bone.—It is not necessary here to dwell upon wounds of bone, since the reader will find all that is practically important in the essays on FRACTURES, GUN-SHOT WOUNDS, and INJURIES OF THE HEAD. Cases of incised wounds of bone without fracture do, it is true, occasionally come under the notice of the surgeon. The chief interest in such injuries lies in the probability of diffuse suppuration (osteo-myelitis) supervening, or of the separation of the periosteum, which is a common event in such cases, leading to necrosis. A reference to those sections will illustrate sufficiently the prognosis and treatment.

T. HOLMES.

¹ See Charcot, 'Lectures on Diseases of the Nervous System,' *New Syd. Soc. Trans.* vol. ii. p. 315.

² Some interesting cases are to be found in Robert, *Conf. de Clinique Chir.* 1861; and many are scattered about in various books and periodicals. I remember seeing at St. George's Hospital, a stout, florid young man who had fractured his thigh in simply walking across his room, without catching his foot or making a false step. It healed like any other fracture.

DISEASES OF THE JOINTS.

IN a sketch such as the present, which must necessarily be brief, any consideration of the diseases of joints in minute detail would be impossible. The writer's aim, therefore, will rather be to present the subject in its broader outlines. It will be divided into two parts.

1. The general pathology, symptomatology, diagnosis, treatment and prognosis of the diseases common to the structures of which joints generally are made up.

2. Their clinical features, as they are found in particular articulations.

These diseases, the result usually of one or other form of inflammation, are of considerable variety, affecting as they do such very different structures as synovial membrane, cartilage, bone and ligament. But, though each of these structures may be the starting-point of morbid processes, it is extremely rare for one bone to be extensively affected without the others becoming involved to a certain extent. Again, each is not affected with the same degree of frequency, far from this. For instance, disease hardly ever begins *primarily* in cartilage or ligament. Of these, the first is non vascular, and its functions are of a purely passive kind; the same almost may be said of the second. Consequently they are far less liable to inflammatory affections than either the synovial membrane or bone, which are both very vascular and possess very active functions. This is why amphiarthrodial joints are so rarely attacked by disease as compared with the diarthrodial. They have but a rudimentary synovial membrane (Luschka¹) and their functions, as well as those of the bones around them, are of a more passive kind. In short, it may be taken as generally true, and this it is well to bear in mind, that the liability to inflammatory disease or neoplastic change of any tissue is in direct proportion to its original physiological functional activity.

The causes, too, which operate in producing these diseases are very various. They may be local or constitutional, or one of these modified by the other. Among the first we find injury, *i.e.* blows, strains, crushes, cuts, punctures, &c., then over-exertion or exposure to extremes of heat and cold. Among the latter we meet conditions which modify the vital processes in all the tissues of the body, but which are many of them particularly prone to produce evil consequences in those of the joints. Some of these are often spoken of as the diathetic joint affections, *i.e.* such as are due to the so-called scrofulous or strumous, the rheumatic and gouty diatheses; while others are set down as produced by the action of certain specific poisons introduced into the system—namely, those met with in pyæmia, syphilis, gonorrhœa, scarlatina, typhoid fevers and some forms of kidney disease. The tendency, however, now-a-days is to abandon the rather vague term diathesis, and to speak of all the constitutional disorders in question as due to the presence in the blood of definite poisons, which either by over-stimulating the tissues of the joints, or by lowering their vitality, bring about the changes in them with which we are familiar. Thus the scrofulous diathesis is now believed by many competent pathologists to be due to the presence in the economy of certain microbia and their products (Billroth, Hueter, Schuller; see **CHANGES OF THE SPINE**). Gouty changes in tissues, on the other hand, are demonstrated to be dependent on the existence in them of a chemical irritant, urate of soda. Chronic rheumatic affections are believed by some to be of an analogous nature. Of the exact *materies morbi* of syphilis we know little or nothing at present, but its

¹ *Die Halbgelenke des mensch. Körpers*, Berlin, 1858. Quoted by Hueter, *l.c.*

fairly uniform effects upon the system show it to be a very definite agent. With the actual toxic principle present in the conditions known as pyæmia and septicæmia we are but scantily acquainted as yet; but, as far as we know anything of the nature of the disease from clinical study and experiment, it seems fair to assume that it is caused by some definite poison produced during the process of putrefaction, probably the product of microbes in the blood. Of the remaining affections, viz. those met with in gonorrhœa, acute rheumatism, scarlatina, and some renal affections, it need only be said that pathologists are more and more inclined to regard them as due merely to varieties of the pyæmic condition, and differing from what are found specially to follow the well-known infection of surgical wounds only in degree of severity. It is suggested that, if these last diseases are produced by organisms in the blood, the variety observed among them may be due to microbes having been cultivated in each case upon a different soil, and so having developed individual peculiarities. (See PYÆMIA, vol. i.)

AFFECTIONS OF THE SYNOVIAL MEMBRANE.

Beginning now with the diarthrodial joints, as of greater importance and more liable to disease, we shall first consider the affections of the most physiologically active of all their component structures, consequently that most frequently the seat of disease, the synovial membrane.

Of the morbid processes to which this is liable, nearly all come under the heading of inflammation. And here we find every gradation between transient hyperæmia, with trifling hypersecretion, and intense congestion with suppuration. Three forms, however, are generally spoken of—(1) the acute, (2) the sub acute, (3) the chronic—all arising from a variety of causes, local or general.

It will be convenient to examine the disease in its simplest forms, first as caused by local influences and independently of any constitutional condition. This will give the type of synovial inflammation, and we need afterwards study the more complicated affections due to constitutional causes only so far as they depart from this type.

The simplest forms of *acute synovitis* are those which follow such injuries as blows, strains, and crushes not opening the joint. With those injuries which open the synovial sac, even by puncture, an extra factor operates in many cases—namely, the introduction locally of septic matter, which modifies the morbid process in a most important way (see pp. 335 and 349). Next to these causes come exposure to extremes of cold or heat, or to wetting.

The vaso-motor disturbance induced by any of these results in rapid dilatation of the vessels of the synovial membrane, with consequent increase in its functional activity, is evidenced by the free hypersecretion of synovial fluid. A joint examined in this condition presents a remarkable appearance on its internal surface. The membrane is of a bright red colour, uniformly or in patches, contrasting markedly with the pearly white of the encrusting cartilages. It is swollen throughout, right up to the border of the latter. The fluid now distending the joint will vary in quantity and quality according to the intensity of the vascular excitement in the membrane. If the latter is moderate, it will present the appearance of ordinary but superabundant synovium. A little later and this fluid is diluted with more or less serum, with a few leucocytes, until finally, in the worst attacks of active congestion, the latter are present in sufficient number to constitute true pus. There is no sharp boundary line between these three conditions, either pathological or clinical; they run into one another.

In the simplest forms of *acute synovitis*, however, it is the rule to find little more than turbidity of the superabundant synovium, hardly sufficient to justify its being called semipurulent. It may contain a few flakes of fibrin and perhaps a shred or two of cast-off lining of the joint.

The symptoms of this condition will be (subjective) pain on movement or handling of the part; local heat and throbbing, with perhaps slight general pyrexia: (objective) distension and fluctuations, with slight redness and altered position.

The general treatment in this state is usually simple. Rest for the joint affected comes first, and must be secured either by position, splints, or other appliances (see special joints). Local antiphlogistics come next, *i.e.* leeches or wet cupping in the case of strong healthy individuals, followed by ice or evaporating lotions to the part in the earliest stages, or hot belladonna fomentations a little later on.¹ The constitutional treatment will consist at the same time of a brisk saline purge, with the addition even of a little antimony in sthenic cases, while in the weak or debilitated tonics and stimulants are often indicated. In a few instances anodynes and sedatives are called for where there is much pain and general systemic disturbance. If there be any suspicion of general septic origin of the attack, quinine or the salicylates should be freely given, together with stimulants.

Under such treatment simple cases do well, and the prognosis is favourable. The hyperæmia becomes less and less, effusion ceases, tension is relieved, and, with the pain, tenderness and local heat, the general pyrexia also disappears. The turbid synovial collection will then be absorbed, and a more or less complete *restitutio ad integrum* take place. Sometimes, however, this absorption is slow, and long after all heat, pain, and redness have disappeared, a serous fluid may still remain behind in large quantity and distend and weaken the joint. This condition, known as *hydrops articuli*, is, however, more likely to follow the sub-acute or chronic affections (see pp. 336-337).

Here it will be necessary to use repeated blistering or, better still, aspiration of the joint with a very fine needle, the utmost precautions as to cleansing the latter and the skin perfectly having been observed. When the fluid has been thus dispersed, the capsular structures so long stretched will require support for a time. This is best given them by careful strapping in the first instance, and later on by elastic web coverings. After this, if there be any stiffness from the adhesion of patches of plastic matter in or about the joint, this may be got rid of by passive movement, which, if painful, may require an anæsthetic. The final absorption of any remains of this plastic matter may be much aided by inunctions of mercurial or iodine ointments, and by friction. Any little weakness left after this will soon be recovered from, as the joint is used, especially if the latter undergo regular douching with cold water (preferably salt), with shampooing.

Such would be the history of a case of simple acute synovitis going as far as effusion of a turbid serous synovium and terminating favourably within a short time. If, however, the inflammation run higher until true pus is rapidly formed, we shall have, in addition to all the subjective and objective symptoms, in a marked degree, above described, several others which will serve to indicate the state of the interior of the joint. Firstly, a rigor is very commonly observed at the commencement of suppuration, then œdema of the part already reddened. If the disease run on, the skin will soon lose its bright red tint, and become of a dusky brownish red, with earthy tracts, until in extreme cases one spot in particular becomes purplish, thinned, and eventually bursts, discharging the contents of the joint. By this time the surfaces of the latter will have assumed a somewhat different aspect to that described above. The synovial membrane will have become more deeply congested and swollen, it will be softened, pulpy and ulcerated, and overlap the encrusting cartilages, causing changes in them, to be alluded to presently (see p. 349).

The treatment of this form of simple synovitis where pus is forming is based upon general principles. The first thing is to empty the joint. This is best done by aspiration or incision. In either case the utmost care must be taken to keep the parts aseptic by careful cleansing of the skin and needle in the first instance and by the use of strict antiseptic dressings (Listerian or other) in the last. The incision should be made on the inner aspect of the joint in the long axis of the limb, but well back, so as to drain the deeper part of the cavity. (R. Parker.) After the latter has been emptied, it may be washed out with 2½ per cent. carbolic solu-

¹ Extr. Bellad. mixed with an equal amount of glycerine is perhaps the most convenient form in which to use this drug. It may thus be easily and gently spread over the tender part, and will relieve pain as well as lower the inflammation.

tion, prior to the adjustment of drain-tubes, and to being enveloped in the absorbent dressings. These latter must be re-applied until the suppuration has ceased and the wound of the joint cavity has closed. When the part has quite cicatrised, the functions of the joint may be completely restored, after an interval of stiffness, if the drainage have been carefully conducted at an early stage. If, however, this opening up of the joint can be avoided, it will be all the better, and, fortunately, a few carefully repeated aspirations are often quite adequate to meet all the exigencies of the case.

During the formation of the pus, and its arrest afterwards, the constitutional treatment will usually require to be a tonic one in the class of cases met with in metropolitan practice, and stimulants will often be needed. In sthenic cases in the country, saline purging, and even bleeding, sometimes may be resorted to with advantage at the outset, but always cautiously, in view of the after condition of the patient. But where, in spite of all antiseptic precautions, the pus within the joint has become contaminated by some ferment from without, every form of general sustaining treatment will be required. Here we shall have the greatest difficulty in saving the joint or limb, if such be the seat of the disease; and not infrequently we are obliged to sacrifice one or the other to save the patient's life. For, in such cases, where the suppuration in the joint becomes foul, the septic fever is usually very high, and the strain upon the patient's powers peculiarly great.

Sub-acute synovitis is produced by the same causes as above which lead to the acute form, but operating in a milder degree. There is consequently less marked hyperæmia of the synovial membrane and less rapid secretion of fluid. The latter consists here of little more than synovium, diluted with a certain proportion of serum, but still quite clear, and containing few or no corpuscular elements. The local heat is only slightly raised, redness and general pyrexia are absent, and the joint is not tensely distended. Pain and tenderness are almost absent, and the part feels little more than stiff. An examination of the surfaces of the articulation shows little departure from the normal, except perhaps slight hyperæmia of the lining membrane in patches.

The treatment in this case will be much the same as in the acute inflammation, but need not be quite so vigorous at first. The chief difficulty here will be, as a rule, to restore the balance between absorption and secretion in the joint, which leads to accumulation of fluid in the joint, usually spoken of as *hydrops articuli*. This condition is more likely to be troublesome now than after the acute affection. If the clear fluid be removed from the joint by blisters or aspiration, it is very apt to re-accumulate over and over again, even without any re-accession of inflammation. It is in this state that, if repeated blisters and aspiration have failed, the injection into the joint of some mildly stimulating fluid, which is at the same time perfectly aseptic, is found of use. The best materials for this purpose are a $2\frac{1}{2}$ per cent. carbolic acid solution or tincture of iodine of the strength of a drachm to the ounce of pure water. The effect of using either of these is, first, to produce a mild inflammation of the synovial membrane, with heat, and refilling of the joint emptied at the time of the operation, and then such a modification of the processes of secretion and absorption as to re-adjust their balance. How this is actually brought about is, perhaps, not as clear as it might be. After these sub-acute attacks, the use of elastic web coverings is often necessary for long periods.

Chronic simple synovitis differs little from the last except in degree. The same causes operate, the same effects are produced. But, owing to some peculiarity in the individual; the latter last longer, and are in consequence somewhat modified. Thus, though the fluid accumulation and the hyperæmia differ in few respects from what is observed in the sub-acute form of disease, the persistence of the latter for long periods leads to plastic thickening of the synovial membrane. It thus becomes altered in consistence, being toughened and heavy, and often irregularly hypertrophied in all its parts. If its borders are particularly affected, pendulous masses of thickened tissue are sometimes formed which hang loose about the sides in the joint (fig. 64). Should one of these become fixed during the movements of the latter, its pedicle may

be torn through, on which it becomes free to move in all directions, and often gives much trouble (see p. 353). Usually with the chronic form of synovitis there is a certain amount of participation of the ligamentous structures around; but this we shall consider later on.

The symptoms of this affection are almost the same as those present in the sub-acute form, only differing in being less marked. Indeed it would not be necessary to consider these two as distinct varieties were it not that the plastic changes in the membrane are important as requiring careful treatment, being prone to very seriously affect the functions of the joint if neglected. In addition, then, to the treatment suitable in sub-acute cases, we have to aim at causing absorption of the plastic matter deposited. This is best done by the combination of pressure by means of strapping with frictions, and the inunction of mercurial ointment, or painting the part with tincture of iodine. The joint should be kept at rest during this treatment, and passive motion should precede for some time the permission to use it. When it is made use of, it should be supported by strapping or elastic bandages for a considerable time, until all tendency to the reproduction of the

hydrops articuli has passed and the part feels quite strong. Douching with sea water and *massage* will also be of use here, combined with the best tonic constitutional treatment we can devise for each patient. If not otherwise contra-indicated, the patient should take outdoor exercise from an early date, the affected joint being carefully protected from movement or strain by some suitable appliance (see special part). Sea-air and sea-bathing are also particularly useful here.

Bearing these three kinds of synovitis produced solely by external causes in our minds as types of simple inflammations of the synovial membrane, we turn now to the consideration of those forms due to constitutional causes. Here the morbid influence acts from within either quite independently of any external agent, or, the latter being present, so modifies its effects as wholly to alter the character of the process it has started.

Under this heading will come the following affections of the synovial tissues -- the pyæmic, scarlatinal, puerperal, the gonorrhœal, polyarthritic rheumatic, and those of typhoid, small-pox, and dysentery; the nephritic, the so-called strumous, and syphilitic, the gouty and chronic rheumatic.

This long list of varieties commonly spoken of may be much shortened if we adopt the view now held by many, that affections of the joints following on putrid changes in ordinary wounds, and those met with in scarlatina and puerperal fever, are really one and the same in kind, the ulceration of the throat in the former, and the foul state of the uterine surface in the latter, being the starting-point in this case. These may then be considered under the common heading of acute pyæmic synovitis. Again, that those often accompanying typhoid fever, small-pox, dysentery, gonorrhœa, some forms of Bright's disease, and that known as polyarthritic or acute rheumatism, are closely allied to the latter, except in being usually less destructive, and may be held to be due to a form of sub-acute pyæmia. Some, again, would go a step further, and regard the gouty and so-called chronic rheumatic affection as both due to one poison, or to two poisons closely allied: but this perhaps with less reason. That a definite toxic agent is present, however, in large quantity in the blood in gout we know positively, and that the liability to inflammation here is in direct proportion to the amount of this in the tissues, is also almost beyond question.

FIG. 64.—Pendulous Growths from the Synovial Membrane. (From a preparation in the Museum of St. George's Hospital.)

This leads us to speculate upon the causes of the other affections of our list. And when we do so in the light of the accurate clinical observation of the present day, and of experimental research, we are driven more and more towards the conclusion, that with *perhaps* the exception of the rheumatic arthritis, they are all due to the presence of definite poisons in the blood, which in some cases act by irritating or overstimulating the tissues through which they are carried, and in others by so interfering with the nutrition of the latter as to cause degenerative changes. What these poisons are in each case we do not definitely know as yet, but about some of them a good deal has been ascertained. That of gout, for instance, we can separate chemically from the tissues, and find it to be urate of soda; that of syphilis we only know through its common mode of introduction into the system and fairly uniform effects, and the influence over it of certain drugs; that of the pyæmic group appears from daily accumulating evidence to consist either in the presence in the blood of certain microbia or some toxic matter produced by them; finally, the excitant of strumous inflammations, it is believed by many competent pathologists, may be almost proved to consist also of lower organisms or their products acting in this case with less energy. (See CARRIES OF SPINE.)

Another point strikes us here in looking over the list of synovial diseases above enumerated—namely, that they arrange themselves easily into three groups, according to the character of the processes which underlie the grosser changes present. One group, including the above acute and sub-acute pyæmic affections, is generally characterised by the presence of active hyperæmia, rapid effusion, and cell-proliferation. The next, made up of the strumous and syphilitic by a more passive hyperæmia and sluggish cell-proliferation. The last, including the gouty and chronic rheumatic, rather by degenerative changes, accompanied or followed by passive hyperæmias of usually moderate intensity, and not marked primarily by either excessive effusion or cell-proliferation. The varieties of disease in each of these groups display a close parallelism in their natural history. For instance, it requires minute scrutiny indeed to detect differences between the chronic pulpy degeneration of the synovial membrane, due to so-called serofula, and the analogous changes of the structure due to syphilis. The same may be said of the other affections of the joints enumerated above as belonging to the acute and sub-acute pyæmic class, while between the primary degenerative changes of gout and chronic rheumatic arthritis there often seems to be a close relation.

With these few general remarks on the synovial affections depending upon constitutional causes, we pass to their more particular study, arranging them in groups for convenience sake according to the above sketch.

Acute pyæmic synovitis is met with, as already noted, in the course of several diseases hitherto held to be quite distinct. It is probable, however, that the poison which produces it is of the same nature in each case, and is introduced into the system in the same way generally in all—namely, through foul suppurating surfaces, whether these be the result of surgical injuries or operations, of contamination of the raw uterine cavity after parturition, or of the scarlatinal inflammation of the throat, ear, or other mucous tracts (for details see PYÆMIA, vol. i.) This agent once entered in sufficient amount seems to possess the power of increasing rapidly to a degree sufficient to produce intoxication of the whole system. This is indicated by an abrupt rise of temperature, culminating in a rigor, after which the temperature may as suddenly fall again. At any time after this one or more of the joints may commence to swell quickly, as a consequence of effusion into them, which, as in the *simple* affection, may be synovial, serous, or purulent.

It is only necessary now to point out briefly how this septic synovitis differs from the typical simple affection described already (pp. 334, 335.) First it may appear in several joints at once, or develop rapidly in one and as quickly subside, while commencing in another perhaps on the opposite side of the body. It is often accompanied by circumscribed pink blushes, which contrast markedly with the pale faded look of the rest of the skin, due to the constitutional conditions, and quite unlike the diffused bright blush of ordinary synovitis. Its effusion in bad cases tends to rupture the synovial

sac early, and to extravasate itself among the peri-articular structures. The affection is rarely limited to the synovial membrane alone, but tends to extend rapidly to the encrusting cartilages, which are evenly and smoothly removed by a process more like digestion than anything else, and usually quite unlike ulceration (see p. 349). This change, too, in the cartilage is not necessarily accompanied by startings of the limb, as in other cases.

The subjective symptoms here are the same as those present in the simple affection running on to suppuration (see pp. 334, 335) and need not be further alluded to. But the constitutional condition is quite different in this case. Here we have all the general disturbances peculiar to the pyæmic state in greater or less degree: the high but fluctuating temperature, the rigors, delirium, restlessness, &c., for the detailed consideration of which the reader is referred to the essay on PYÆMIA.

As to the ætiology of the local affection, we have started with the justifiable assumption that it is due to a poison circulating in the blood, and there only remains to be considered how this produces the inflammation of the synovial membrane. The most satisfactory theory to account for this appears to be briefly the following. That the septic matter in the circulation acts as an irritant upon all the vascular structures of the body. That all are thereby excited to increased function for the time being. That those of them which preside over the secretion of the various fluids of the body give evidence of this in the increased amount they produce. Thus, for instance, the intestine may give off much mucus; the lung likewise in the case of the enteritis or bronchitis so frequently observed in typical pyæmia. But in both these and other instances, the secretion containing some of the poison from the blood is cast out of the system. In the case of the synovial cavities, however, this is not so. Their secretions are thrown off into a closed sac, from which there is no escape except by absorption. But the fluid in this case contains a poison eliminated from the blood, as offending material, and is therefore a strong local irritant. We have, therefore, not only the original stimulus to inflammation of the synovial membrane, due to the poison in the blood, but this plus the active irritant of the septic synovium, pent up and ever increasing in the joint. It is probably for this reason that we find free effusions into synovial cavities in septic conditions of the system where the poison is not present in sufficient amount to produce very marked outpourings of secretion from free surfaces (*e.g.* intestine, lung), where there is no accumulation of the *materies morbi* for any time. With the varying virulence of the poison, too, there will be a difference in the intensity of the inflammation in the joint, and we may find a simple synovial, a serous, or a purulent effusion into it. The last of these, charged with septic matter (whatsoever this be), now acts as an intense irritant upon the cartilage, causing rapid proliferation of its cells and solution of the matrix in a way to be described hereafter (see pp. 349-350).

The diagnosis of these affections is rarely difficult in view of the general condition, and requires no special notice.

The local treatment, too, is conducted on the same principles laid down for the simple affection; the necessity for early evacuation of the septic effusion from the joint by aspiration or incision being particularly urgent here (see p. 335). In addition, we have to employ those measures for dealing with the general condition mentioned in the essay on PYÆMIA. Our chief reliance here will be upon quinine in large doses, combined with the free use of the stronger stimulants.

The prognosis in acute cases is gloomy, both as regards the joint and the life of the patient. Where the septic irritant is present in sufficient amount to cause free suppuration in the articulation, as is often the case, it is only too likely to be abundant enough to produce fatal general toxic effects upon the system too. But where the poison is less virulent, or the patient strong enough to resist it, there may be recovery after more or less disorganisation of the joint, followed by ankylosis.

In the synovitis often accompanying gonorrhœa, typhoid fever, small-pox, dysentery, the so-called poly-arthritic rheumatism, and some forms of renal disease, we have but milder forms of the affection just considered. Either the dose of the poison in these cases is smaller, or it is less virulent, or the patient's vitality is greater: the

results, therefore, are not so bad in most cases. This is not always so, however. Fatal pyæmia has been known to follow gonorrhœa in several cases.¹ I have also had to treat a case in which, during typhoid fever, rapid effusion into the right hip-joint had gone on to softening of the capsule, and slipping out of the head of the femur upon the dorsum ilii, from which I was able to reduce it again into the acetabulum. But in the majority of cases, the form of synovitis following the diseases mentioned above is of a milder character than that of the first class. How the septic matter is introduced in each case is not always certain. But we can readily understand the possibility of its reception from the inflamed or ulcerated urethra, from ulcers in the intestine, or pustules on the skin, &c. I am also inclined to think, from numerous observations, that suppuration of the middle ear is a more frequent source of septic intoxication than is commonly supposed, and is often overlooked in such cases. I have seen poly-arthritic synovitis traceable to nothing if not to *otitis media purulenta*.

In this group of sub-acute septic synovitis, the temperature usually rises very considerably, often four or five degrees, but does not oscillate so much as in the first group; rigors, too, are not so frequently observed. The inflammation of the joint is not so rapid in its course, and often produces but slight effusion, with puffiness, and a faint blush which soon fades. The pain is usually very severe, perhaps more so than in the severer cases, but it is rather on movement than from distension, &c. Here, too, there is the same tendency as in the first group for the disease to affect one synovial tract after another, or several at a time, none in the body having immunity, not even the tendinous sheaths and bursæ. The possibility of the smaller 'out of the way' joints being affected in this way should always be borne in mind as explaining, perhaps, many of those deep-seated pains and swellings occurring in the course of the diseases enumerated above, in situations in which we are not familiar with synovitis. Thus any of the small articulations of the vertebral column may be affected as well as bursæ to whose existence even our attention would otherwise hardly ever be called.

In *gonorrhœa*, the joint affection generally starts about the second or third week after the appearance of the purulent discharge, but there is no great regularity in this matter. In the other diseases, it may start at any time during their existence; that is, as long as they are accompanied by suppurating surfaces which present a suitable soil for the reception of the accidental inoculation. In all the affections of the sub-acute specific group, but perhaps especially in that following gonorrhœal urethritis, the synovitis leaves the joint in a condition in which recurrence of passive effusion is frequent: it appears, too, to remain longer painful than after the simple affections. It may also degenerate into the chronic form, with much plastic exudation both in the synovial membrane and in the parts around, leading to much stiffness of the part.

The diagnosis of the nature of the synovial affections of this group is not difficult, if we bear in mind the possible constitutional causes alluded to.

The treatment, too, apart from the cleansing, if possible, of the original focus of absorption, and correcting the general septic condition, offers no material points of difference from that described as suitable in the *simple* form of subacute synovitis (see p. 336).

We turn now to that group of so-called constitutional synovial affections characterised in the main as we have seen (p. 338) by a more passive hyperæmia, and sluggish cell-proliferation. This group will include *sypilitic* and *strumous* synovitis.

It is necessary to remark, however, that we are not including here that form of sub-acute synovitis often noticed early in the secondary stage of syphilis, which differs little, if at all, from what we have been considering under the head of sub-acute septic synovitis. The congestion and hypersecretion here in the joints are analogous to what is often observed at the same time in the mucous membrane of the throat, larynx, and bronchi, at the outset of the secondary sequelæ, which last for a short

¹ Wilks and Moxon, *Path. Anat.* 2nd ed. p. 70.

period, and disappear spontaneously, but only to be followed soon by the more obvious cutaneous syphilides. The synovitis here is probably due to the irritation of the poison, which as yet is not sufficiently developed to produce those plastic tissue changes familiar to us in the later secondary and tertiary stages. It is probably this milder form of synovial affection, without marked effusion, which gives rise to those 'prodromal pains' in the joints and deeper parts of the back so often met with at the onset of syphilis. Possibly the joints of the spine are the seat of some of them, as well as those larger articulations which we can see and which are usually the seat of pains too.

But the syphilitic synovitis which is here grouped with the strumous is not this. It is that slow structural change in the synovial membrane coming on late in the disease, whether acquired or congenital. For in the latter form it occurs quite as often, if not more so, than in the former. Any or every structure of a joint may be affected, but the bulk of the disease is generally observed in the soft parts, especially the synovial tissues. Here we are dealing with a small colled infiltration, usually most abundant in the latter. To the naked eye, its appearance differs but little, if at all, from the granulation-tissue of the chronic strumous affection. When the cells are aggregated in distinct masses, we have the true gumma before us. But usually it is distributed evenly like inflammatory exudation (although there is but slight hyperæmia present, and that of a sluggish, passive character), throughout the whole synovial tissues, giving the latter a softened pulpy consistence, and a swollen appearance. In this condition it may remain for a long time, if not removed by treatment, or may undergo further secondary changes. The latter will be quite analogous to what takes place in the pulpy granulation of struma. It may become converted into fibrous tissue, or may liquefy, caseate, or become converted into cretaceous matter. Thus, as we shall presently see, there is in both syphilis and struma either (1) a return to the healthy state, with or without permanent thickening; (2) liquefaction of the lowly-organised granulation-tissue and the formation of larger or smaller collections of soft broken-down material which may burst its way through the skin or into the joint; (3) the conversion of this same tissue by a process of fatty degeneration into cheesy masses in the neighbourhood of the latter, or (4) its drying up into cretaceous matter in the same situation. If the deposit be present in the actually granulating form, it will, if it break down, usually follow the rule which applies to external gummata elsewhere—namely, progress more or less rapidly towards the surface of the body, and open eventually upon it. It may then, however, degenerate progressively towards its base, until it secondarily opens into the joint (see Coulson's case¹). This, too, shows a close parallel with the strumous affection. Sometimes, but not as a rule, this tertiary deposit in the synovial structures provokes an effusion into the joint.

These tertiary syphilitic lesions have been long recognised clinically, but Lancereaux² was one of the first to demonstrate the condition by post-mortem examination. In his interesting description the clearest proof is given that the tertiary deposits or inflammatory products in the articular structures present the same characters and undergo the same changes as elsewhere in the body, as indeed we might expect.

As to hereditary syphilitic disease of the synovial structures, recent observations tend to show that the same condition may be expected to, and does, appear here as in the late tertiary acquired form. There is much need, however, of further careful study of this point.

The subjective symptoms of this late syphilitic affection of the synovial structures are usually not well marked. There may be very extensive invasion before either much pain, weakness, or stiffness are complained of, and a patient will often continue to use the part when an amount of swelling, &c. is present, which, were the disease strumous, would indicate very extensive and disabling destruction, and be accompanied by considerable suffering. The objective symptoms are: swelling, usually far less uniform than in the strumous affection, and possibly localised at one or two

¹ *Lancet*, vol. i. 1858.

² 'Des Arthrites Syphilitiques,' *L'Union Méd.* 1873, No. 88.

spots into lumps which may have the elastic or doughy feel of fresh or degenerating gummata respectively. At the same time there will be little or no rise of local temperature, or other signs of active congestion. The colour, too, will be unchanged, unless any gummatous deposit is approaching the surface, or have broken through the latter, when the well-known brownish-purple lividity will be marked at that spot, contrasting notably with the usual earthy tone of the rest of the surface, so often seen in late syphilis. The diagnosis is also much helped if there be in other parts of the body evidences of the disease in one or other of its numerous forms. When the affection is congenital, some of these may be, as I have seen, interstitial keratitis and the 'pegged teeth' so often found with this disease.

The treatment of this form of joint disease is usually more satisfactory than that of the strumous variety, unless it have advanced to such an extreme degree as in Lancereaux's case, and be accompanied by such a hopeless cachexia. Our chief reliance with younger individuals will be on alternative doses of mercury: under its use, combined with rest, change of air, cod-liver oil, tonics, and careful dieting, the symptoms will often rapidly disappear. Among the more aged and cachectic, iodide of potassium, in doses increasing daily if necessary to as much as a drachm three times a day, in largely diluted solution, is preferable to mercury, the same tonic treatment being used in both. Where complete restoration of the joint takes place, it may be marked on its surface by pits or depressions corresponding to subcutaneous contractions in the healing gummatous collections.

In turning now to strumous disease of the synovial membrane, we must leave the detailed discussion of the constitutional condition to the essay on SCROFULA, vol. i. (see also CRIES OF THE SPINE), and direct our attention chiefly to the local changes.

This is essentially a disease of early life, met with mostly in those whose general vitality is low, and who are surrounded by defective hygienic conditions. Some pathologists see in the last factors adequate reason for the low inflammation and subsequent degenerative changes characteristic of the disease. They regard the inflammation as started by some external influence (such as slight injury or exposure) in tissues of less than ordinary vitality, easily yielding in the first place to the morbid stimulus, and in the next deficient in power to recover their lost balance after the latter is exhausted, and therefore slowly undergoing degenerative change. Others, again, admitting the deficient vital force inherited or due to mal-hygiene, believe that this is a factor in the disease only so far as it renders the tissues incapable of withstanding the attacks of minute organisms introduced into the blood through some of the superficial ulcerations of the skin or mucous surfaces so frequent in childhood (see CRIES OF SPINE). These microbes, which, in a fairly healthy body, would be neutralised or annihilated by a superior force in the human cells, are able in the enfeebled body to multiply enormously, and eventually to gain the upper hand in situations especially where, perhaps owing to a slight injury, the local vitality is still further lowered, where they form colonies and work particular mischief.

Whatever be the value of these theories as to causation, the changes in the synovial tissues in struma are fairly plain. We find in the first place sluggish hyperæmia, accompanied by slight hypersecretion, then cell exudation and proliferation in the synovial and peri-synovial, or even capsular structures, until all are converted more or less into a material resembling granulation-tissue. This is the 'pulpy softening' of synovial membranes so often spoken of. This soft tissue may now undergo various changes. With a return to health, it may be absorbed or converted more or less into fibrous tissue, producing in the last case some thickening and induration of the synovial structures. With persistence of the evil, the exudation and softening may gradually extend to the ligaments and bones, or, the hypertrophied swollen synovial fringes spreading between the latter, may convey the irritant to the surfaces of the cartilage and lead to their destruction (see pp. 349-350). And beyond this the granulation-tissue may itself alter in structure. It may either degenerate rapidly, forming small cold abscesses full of curdy material, or it may caseate slowly in patches producing soft cheesy foci of greater or less size and consistency. These latter, and even the small

abscesses, may with returning health become absorbed before rupture, or converted into cretaceous nodules; but, as a rule, sooner or later they make their way further and burst, either through the skin or into the joint, though not so frequently in the latter direction as is supposed.

The objective symptoms of this disease of the synovial membrane, commonly called 'white swelling,' upon which we base our diagnosis, are slight heat with little or no redness, swelling of the joints (best seen where the capsular structures are thinnest), usually of an elastic consistence, or doughy if caseous degeneration be in process; slight effusion in some cases with fluctuation. Subjectively we find very little: slight throbbing and uneasiness may be complained of, but pain is not marked, unless the part be moved or unless the bone be also diseased, when it will be gnawing in character, especially at night. There is no starting of the limb in simple cases.

The general treatment of the two conditions, strumous and syphilitic disease of the synovial membranes, is entirely the same up to a certain point. Constitutionally, everything is aimed at which can possibly raise the vitality of the whole system; hence abundance of suitable food, good clothing and fresh air, dry and not too cold, are called for, with tonics, cod-liver oil, and alteratives, either mercurial or consisting of the iodine preparations. Locally, complete rest for the part, with active counter-irritation in the earlier stages of the strumous affection, not in the syphilitic. This should consist in repeated blistering, painting with iodine tincture, or, in chronic cases, the application of the actual cautery to the skin over the affected joint, either to produce mere vesication or an open sore.

But besides all this some special methods of treatment deserve a few words of notice. Thus the influence of mercurialunction, combined with firm and even pressure, kept up upon the part by means of strapping, is regarded by some as particularly valuable where it can be applied. It is supposed that the absorbent action of the mercury is here aided by the even pressure. Others employ elastic bandaging,¹ alternating with shampooing, but without absorbent applications. It is supposed in this case, that the elastic bandage, applied each day for a certain time, will tend to unload the passively engorged vessels, while the stimulus of rubbing and chafing the part encourages a more active vascularity. This line of treatment deserves a fair trial. Again, on the theory that strumous inflammation is due to the presence of microbes in the blood, another method of treatment has been proposed and practised by Hueter—namely, the injection of small quantities of a two and a half to five per cent. solution of carbolic acid into the synovial tissues by means of a hypodermic syringe. This is supposed to remove the source of inflammatory irritation, by destroying the colonies of organisms presumed to be present. The proceeding itself is simple, consisting merely in so injecting the solution, ten to fifteen minims at a time around the joint, that the area of diffusion from each puncture shall overlap the last somewhat. This has to be repeated over and over again at intervals of a few days. Professor Hueter claims for this method a prominent place among the modes of treatment both of strumous disease of the synovial membrane and of bone. And it would be well, perhaps, if a fair trial were given to it on the recommendation of so good an authority; it is hard, at least, to see how it could do any harm to either the joint or the system.

The next group of joint affections which must engage us for a few moments is characterised primarily neither by effusion nor cell-proliferation (although these are present secondarily in many cases); we have here changes which resemble degeneration more than anything else. But, though the diseases belonging to it are here considered in connection with the synovial affections for convenience sake, it may at once be stated that the morbid changes of this group are not limited to the synovial membrane, but almost invariably involve each and all the structures of the articulation eventually. This is particularly true of *gout*, the first of the group. That the articular changes here are due to the presence of a definite chemical poison there can be no doubt. This is well known now to be urate of soda, whose existence

¹ Martin, *Trans. Internat. Med. Cong.* 1881, vol. ii. p. 444.

in the blood and tissues is due to those errors of digestion consequent usually upon the too abundant use of nitrogenous food and habits of life hostile to healthy combustion and elimination. This substance appears to deposit itself in the solid form by preference in the tissues of lowest vitality, *i.e.* in cartilage ligaments and capsular structures especially of the extremities, less so in the vascular synovial tissue proper and in the bones, rarely in the highly organised parenchymatous structures. The question then suggests itself whether this deposition may not be due, at all events in part, to the lack of vitality in the tissues mentioned, owing to which they are unable to eliminate or resist the power of the salt to crystallise, which it does therefore in tufts of acicular prisms. In solution, too, it passes into the joint with the synovium, and is there precipitated in crystalline form, and often in sufficient amount to distend the synovial sac with a mass resembling chalk. It is the presence of this product which is supposed to provoke that hyperæmia which culminates in the explosive attacks of inflammation of the peri-articular structures so familiar to physicians. It is probable, also, that its existence in solution produces a lowering of vitality in the tissues in which it is found, laying them open to the degenerative changes which are found. The characteristics, then, are the gradual deposit of urate of soda in the articular structures, commencing in those of least vitality and slowly involving the others. The hyperæmias and subsequent degenerative changes are but consequences of this deposition. For any further description of the disease and its treatment the reader is referred to medical works. It is described here thus far for completeness sake, but is commonly regarded rather as a medical than as a surgical ailment.

The remaining disease of this group has apparently much in common with gout in its general characters, but still differs from it in so many important particulars as to deserve a special name. What this should be is a difficulty: it has been known variously as *arthritis deformans*, *rheumatic gout*, *chronic rheumatic arthritis*, *chronic osteo-arthritis*, *arthritis senilis*, *arthritis sicca*, or *nodosa*, and lately has been dubbed *polypanarthritis*! To most of these names there are objections which need not be considered here; to the first perhaps least, as it describes the affection generally without implying any theory as to its causation, about which there is still ample room for discussion.

Arthritis deformans is essentially a disease of advanced life, occurring in a vast majority of cases after the age of fifty. In some few instances it will be met with earlier in feeble patients. Among the ill-fed and clothed it is far more common than among the upper classes, differing thus from gout, with which it has otherwise much in common. Indeed it is sometimes familiarly known as 'poor man's gout.' Habitual exposure to vicissitudes of weather appears to dispose to it, but whether by acting locally upon the joints or, as seems more probable, by affecting the general nutrition of the body, is not determined. The disease, then, to many pathologists appears on these general grounds at all events to commence in some loss of vitality in the tissues, owing to one or more of the above influences, which leads to degenerative changes. As the condition advances, however, the introduction of other secondary factors is recognised in the shape of low inflammatory processes due to the disturbance of function in the first instance by the degenerative changes. It would be incorrect, then, to describe it in the form commonly met with as purely degenerative, seeing that its most to be deplored results are those produced by secondary inflammation, and this not even always destructive, but often of a plastic character.

If we look into a joint in which this affection is in its earliest stages, many striking changes may be observed even with the naked eye. In the first place, the encrusting cartilage may appear roughened, and on close examination fibrillated, but without any evidence of inflammation. This alteration is supposed to be the result of degeneration of the cartilage cells and their removal, leaving behind the intercellular matrix in the form of columns or fibres. It may be due to age, exposure, unhealthy poison-containing blood reducing the vitality of all the tissues, or, to all these causes combined. This is probably the first change of all in this disease, and

before it has progressed very far leads to actual loss of substance in the cartilage. For, the latter in its degenerated condition appears unable to fulfil its functions, and is gradually worn away in the movements of the limb, until eventually bone surface meets bone surface. Another condition may be noticed at the borders of the encrusting cartilage, advancing *pari passu* with the change just described. This is an irregular swelling of the tissue producing small eminences of a pearly hyaline look or yellowish colour. They are noticed at those parts of the surface least used in the ordinary movements of the joint—namely, at the borders of the encrusting tissue, where it is close to the periosteal and synovial vascular supply, and only interfere with the smoothness of play of the latter during its extraordinary movements. These little eminences are undoubtedly due to hyperplasia of the cartilage. And this hyperplasia is explained either by the irritation produced by the play of those parts of the joint surfaces which are undergoing degeneration against one another in

Chronic Osteo-arthritis of the Knee-joint. (From a preparation in the Museum of the Middlesex Hospital)

FIG. 65.—Anterior view.

FIG. 66.—Posterior view.

their roughened state, or by the presence in the blood of some irritating matter. But the first of these seems the more likely hypothesis. Slight congestion is also observed in the nearest vascular tissue, *i.e.* the synovial membrane, but not sufficient in most cases to do more than produce trifling hypersecretion. This irritation of the synovial membrane was supposed by Cruveilhier, Adams, and Sir B. Brodie to be the initial change; but, as stated, there appears to be an earlier degenerative one in the cartilage. As the disease advances, however, and the cartilage becomes more and more worn away until bone actually plays against bone, the irritation becomes greater. The cartilage at the borders becomes more lumpy, the irritated bone commences to throw out osseous tissue at the periphery of the joint, while worn and eroded by friction at the points of contact. All this is a slow process, and the new osteophytes are made up of a soft spongy tissue, likened by Billroth to 'tallow drippings,' which during the movements of the joint is moulded more or less so as to accommodate the latter. The synovial membrane too becomes thickened and roughened,

and covered in many cases with hyperplastic fringes or pendulous growths. These latter occasionally become detached in the movements of the joint, and form loose bodies.¹ Or they may become ossified, and then detached, forming what are known as 'aditamentary bones.' Figs. 65 and 66² illustrate the condition of a joint in this stage. We see the worn surface of the femur where it played against the tibia, the large masses of new bone-tissue which has been formed around the ends of both bones, forming at one or two spots 'aditamentary' bodies. It is the presence of this new osseous material which gives the nodular appearance and feel to the part as seen and felt through the skin, and which sometimes so completely surrounds the joint ends as practically to prevent all movement. Here there is no true synostosis, or fusing of the bones together; they are simply locked one into the other. But the above is not always the exact course of things. In some individuals the degenerative process appears to progress very slowly, the tissues having for some cause more vitality. Here the cartilage only disintegrates very tardily, and the underlying bone is thus brought under the influence of direct pressure by easy gradations. The consequence is an osteitis differing from the plastic described only in being less active; by this process deposit takes place in the porous ends of the bones themselves, thus rendering them very dense. This sclerosis now further prevents any rapid destruction, one hard surface meeting another equally so. And in playing one upon another the surfaces become worn extremely smooth, and, being hard, eventually take a polish as bright as that of porcelain or ivory, which is not seen so long as they are soft. In this state the movements of the joint may be tolerably even, although dry creaking will be felt by the hand placed externally.

Occasionally, but very rarely, the degenerative changes go so far as to produce a kind of caseous suppurative in the joint. In this case we shall find patches of infection within the latter, with here and there breaking down of the bone and last traces of the synovial tissues into curdy material, which is found floating in the turbid fluid now more or less filling the joint. Such a state of things may last for months or years, the exterior of the joint being more or less discoloured in patches, swollen and doughy, but hardly presenting any signs of inflammation.³ The fluid may then be slowly absorbed, and the softened surfaces of the bones mould themselves as above described, until they eventually lock. On the other hand, the fluid, with its curdy admixture, may slowly work its way to the surface with but slight inflammatory disturbance, and at last perforate the skin, discharging for a longer or shorter period. In this state the cavity is apt to be infected with some septic matter sooner or later, completely altering the complexion of the case. The process now becomes actively inflammatory, with free suppuration, and may soon destroy the articulation or the patient's life if the diseased parts be not removed by a timely operation.

All these various phases of *arthritis deformans* are accompanied by symptoms subjective and objective. In the earliest stages, when the cartilage is degenerating, the patient will first notice some uneasiness and creaking in the joints, with slight weakness and insecurity in putting it to its work. Nothing objective can now be made out except that the roughened surfaces actually do creak under the hand on movement. A little later, when the low inflammatory action is beginning, and the border of the cartilage is in a state of hyperplasia and is becoming nodular, while the synovial tissue is irritated, pain is complained of both constant and on motion. The latter, too, is also accompanied by much greater creaking or crackling. Objectively there is also lumpy enlargement of the borders of the joint, which may now contain more fluid than usual; there may be very slight heat about it too, but no redness. Its

² De Morgan, *Trans. Path. Soc.* vol. xix. p. 319.

³ Some years ago I had an opportunity of dissecting a joint in this condition after death, in which there was besides the distinctive change on its surfaces, a well-defined abscess in the head of the tibia, which had opened into the articulation, just as one sees in the strumous disease. The other joints of the body showed advanced arthritis deformans. This condition suggested very forcibly the possibility of hybrid disease, to which attention has recently been called by Professor Verneuil at the International Medical Congress. See *Trans.* vol. ii. p. 373.

movements again are more or less interfered with, not only owing to pain, but also to the presence around the free margins of the articular surfaces of the eminences and nodules alluded to. Any attempt then to flex to the full extent of a normal joint puts the lateral and other ligaments on the stretch, thus causing increased suffering. With each further stage of the disease these symptoms become more marked, especially the last—namely, limitation of movement. Eventually, if the joint becomes quite locked, no pain will be felt. If breaking down of the structures of the joint occurs, the objective symptoms will be, some œdema, redness, swelling and fluctuation, but never to the degree met with in ordinary inflammation; the pain, too, is not so severe, nor the heat and throbbing, the whole process being very indolent.

Few joints in the body, if any, have immunity from this disease, but some appear to be more frequently affected than others. Among the larger articulations, the following is about the order of frequency: hip, knee, shoulder, elbow, ankle, sternoclavicular and temporo-maxillary, the smaller joints showing it only a little less frequently; even the vertebral joints may be extensively involved in the disease.

Both sexes appear equally liable to arthritis deformans, but it has been noted by Haygarth and Adams that the larger joints are more frequently attacked in males, the smaller in females.

When we turn to the question of the treatment of this affection, we are not encouraged by any results that have hitherto been obtained. Cure of the condition when marked there is none known; the structural changes cannot be repaired. The most that can be said upon the subject is that we can probably help to arrest the disease before it has become very advanced, or in the latter case to relieve to some extent the suffering produced by it. Regarding the whole condition as commencing in degenerative changes, we can improve the vitality of all the tissues by ordering good, nourishing, but light digestible food, careful clothing, fresh air and tonics, or, if the vitality of the tissues be lowered by the excesses of eating or drinking surcharging the blood with deleterious matters, we can, by regulating and simplifying the diet, encouraging the action of the skin by Turkish baths, and other eliminating organs, advance in the same direction. Locally the nutrition of the part may be helped by protecting it from exposure to the vicissitudes of climate by means of coverings of cotton-wool or flannel; also by systematic rubbings, with or without stimulating liniments, all round the part affected. Douches and hot baths for the latter are also sometimes of use, and even counter-irritation may be resorted to occasionally. Pain may be relieved by the local application of anodynes in the form of liniments, belladonna or opium being preferred. Small doses of iodide of potassium, too, with carbonate of lithia, I have often noticed have more or less power of relieving the pain of this disease, though how is hard to say. Numbers of other drugs have also been given, but their very number and variety show that no one among them has proved constantly useful.

Of the benefits, on the other hand, accruing from residence at some of the bath resorts, I think there can be little doubt. Wherein the particular virtues of these places lie, whether in the particular quality of the water drunk, or in the action of the baths upon the local or general condition, or in the regular habits of life and careful dietary, it is impossible to say in every case. But of this I am satisfied, that patients whom I have known have been much benefited by a sojourn at Wildbad, for instance, when other treatment appeared to lead to no good results. The other resorts generally regarded as beneficial in this disease are Buxton, in England, Luchon, in the Pyrenees, Vichy, Ems, Wiesbaden and Carlsbad. But of all I would give the preference to Wildbad, which, for some reason or other, appears peculiarly suited as a resort for those affected with arthritis deformans, rheumatism and gout.

AFFECTIÖNS OF THE LIGAMENTS.

The affections of the *ligamentous structures* of joints have next to be considered, and can be disposed of briefly. For here it is nearly always a question of extension of disease, either from the bone or synovial membrane. Primary disease of ligaments

is extremely rare for reasons already given (p. 333). Occasionally, however, after some severe strain or stretching, they become the seat of inflammation. This is usually sluggish, the tissue affected being normally far from vascular and consisting of very highly developed connective-tissue with few embryonic elements in it. After such an injury, too, the other structures of the joint are often also involved in the inflammation, and this may mask the condition of the ligaments. The latter, if inflamed, will be found somewhat injected with vessels passing among their tough fibres, and if this hyperæmia be not soon reduced, also softened and thickened by plastic exudation. The diagnosis of such an injury, in the first place, would not be difficult in view of the history, probable ecchymosis, localised pain and tenderness increased by particular movements. The subsequent inflammation would be indicated by heat, throbbing, swelling, and increase of pain, in addition to the first evidence of injury. There might also be some effusion into the joint if the synovial membrane had become irritated. The treatment of ordinary cases of inflammation after strain of ligaments is plain: complete rest for the part, with local depletion by leeches or wet cupping; ice in the early stages, hot belladonna fomentations in the later. When all evidence of inflammation had subsided, the part would require (if the joint be suited to it) firm strapping with adhesive plaster to support the weakened ligaments and prevent passive congestion. Indeed, if bad strains or 'sprains' be seen early enough before inflammatory reaction has commenced, they may be most advantageously treated in most joints by well-applied strapping from the very first, combined with complete rest.

In weakly individuals of low vitality this hyperæmia of the ligamentous structures after injury is very prone to become chronic and to lead to much softening and swelling. Again the ligaments may become gradually involved in disease which has had its starting-point either in the synovial tissues or the bone. Here the changes will be the same as in the much rarer primary disease, and will be usually much more extensive than in the latter (see p. 342).

AFFECTIONS OF THE CARTILAGES.

When we come to consider the *primary* changes in cartilage, we find that, as in the case of other non-vascular tissues, whose functions are of a passive order (*e.g.* cornea, arterial coats) they are almost solely degenerative. When the cartilage shows any active change, it is almost invariably secondary to an active process approaching it from one of its surfaces, not starting in itself. But the degenerative alterations of its structure are primary. They depend upon a loss of vitality in its cells, by virtue of which fatty change takes place in the latter. In cartilage, thus affected, small oil globules are to be seen packed around the nucleus of the cartilage corpuscles and replacing their protoplasm. The matrix thus losing its centres of vitality, degenerates and cracks upon its surface, the innumerable fissures deepening as the process advances, until the appearance of the encrusting material is that of some 'pile' fabric, such as velvet, or, when the finger is passed over it, may look like a field of corn beaten down by the wind. Sometimes there is also seen a deposit of small fatty granules in the matrix itself, lying in rows vertical to the surface, and along these lines the splitting of the tissue takes place. Such changes are constantly met with during post-mortem examinations where no evidence of joint disease had been observed during life. It appears probable that they may be due to age in some cases, though in many aged people they are absent. It is better, however, to regard them generally as depending upon the same conditions which lead to fatty degeneration elsewhere—namely, loss of vitality. We can then view the latter as depending upon age, lack of sufficient food, or the circulation in the blood of deleterious matters interfering with the nutrition of the tissues. That the latter cause may operate is shown by the analogous condition of cartilage produced in gout. Here, as the result of either errors of assimilation or elimination or both, a harmful matter accumulates in the blood, and is carried by it through all the tissues of the body, inducing changes already alluded to (p. 344). When very abundant in the blood this urate of soda is

deposited in the cartilage, and may give the latter almost a chalky appearance. Its presence here leads to lowering of the vitality of the tissue, which consequently undergoes degenerative changes, its matrix breaking up as in the above fatty change, and finally being completely absorbed. But it is probable that similar hurtful matters, may produce the like lowering of vitality in tissues, while in solution in the blood and plasma, as we see these do when actually precipitated in the solid form. This, if true, would probably account for the changes in the encrusting cartilages which we suppose to be the starting-point of arthritis deformans (p. 314), which have a certain resemblance to those of gout, though the actual hurtful material is unknown. These degenerative changes, then, whatever their cause, are almost the only known primary diseases of the cartilages of joints. That pearly swelling of the borders of the latter alluded to as present in the early stages of arthritis deformans is probably only a secondary hyperplasia, due to the irritation produced by the bone surfaces coming into contact as the cartilage over the ends degenerates. As to new growths springing from articular cartilage, they are almost unknown.

Secondarily, however, joint cartilage is affected by inflammation as any other connective-tissue. That is to say, if any strong irritant be brought into contact with either of its surfaces, its cells go through the same proliferative changes as those of the group of tissues to which it belongs, and the intercellular material is similarly altered thereby.

The usual causes of inflammatory destruction of cartilage are either strumous or one or other form of septic synovitis, whether produced by direct infection of the joint, or systemic intoxication, or strumous disease of the underlying bone. The destructive process varies only in degree with each of these causes, and need only so far be described for each.

When such a state of simple acute synovitis exists as that sketched at (pp. 335 and 336) the products of inflammation are brought into contact with the surfaces of the cartilage, either by the overlapping of the congested fringes of the synovial membrane or by the pus effused. These act as irritants upon the cartilage, whose corpuscles consequently commence to proliferate until those 'mother capsules' nearest the surface are distended with small round indifferent cells. This distension goes on to rupture of the capsules towards the joint, thus producing little pits upon its surfaces. Through these depressions the irritants now reach deeper still, causing the same proliferative changes in the next series of cells, which likewise burst into the joint. In this way the encrusting covering may be honeycombed even as far as the underlying bone. Between these hollows or ulcers (fig. 67), if we choose to call them so, there remains for a time a certain amount of the original intercellular matrix of the cartilage in the form of columns or filaments. But not for long; for their nutrition is so much interfered with by the changes in the capsules, that they rapidly break down and dissolve, and thus all the elements of the cartilage are destroyed (fig. 68). Sometimes, however, as in strumous synovitis, where inflammation is sluggish, the cartilage is only pitted here and there over its surface by these small ulcers, leaving healthy tissue between, or is eroded simply at its margins in a line corresponding to the inflamed synovial membrane overlapping it.

FIG. 67.—Incipient Ulceration of Cartilage. (Museum of St. George's Hospital.)

FIG. 68.—Ulceration of Cartilage. (From a preparation in the Museum of St. George's Hospital.)

Where the stimulus or irritant is very potent in the joint, on the other hand, *e.g.* where septic pus is present, the process is essentially the same as in simple suppurative synovitis, except that the intensity of the process of destruction is so great that the matrix is dissolved *pari passu* with the proliferation of the cells within the capsules and the bursting of the latter, and as a consequence we do not usually find pits or ulcers on the cartilage, but a general removal of all its constituents simultaneously. Under these conditions the cartilage presents the appearance as though its surface had been digested or dissolved away by some corrosive fluid poured upon it. It is thinned either uniformly or over tracts, but smoothly, and without any notable change of colour, so that it may look at first sight as hardly altered at all, with the exception of being extremely thin. A section of what remains, however, will show the proliferation of its cells taking place rapidly.

But cartilage may be equally destroyed by inflammatory stimulus reaching it from below through the underlying bone. The process here is almost identical with what we have just seen. It may be rapid, or slow, which is more common. In a case, for instance, of rarefying non-suppurative osteitis in the end of a bone, where the inflamed medulla is expanding at the expense of the true osseous substance in all directions, it comes eventually to press against the under surface of the encrusting cartilage. The cells of the latter now commence to proliferate, as already described, and the capsules to burst—this time, however, towards the centre of inflammation, *i.e.* the bone. The inflamed medulla now enters the pits thus formed, and so carries the stimulus to the next series of cartilage cells, which go through the same process, again admitting the medulla a step further. Finally it will be found that the latter has pushed its way quite through the encrusting cartilage into the joint, and now forms islands of granulation on the surfaces of the latter tissue, in the middle of otherwise healthy cartilage. Vertical sections will show these islands to be nothing more than the apices of bosses of the inflamed medulla of the bone beneath, which have tunnelled up from below. When the granulation-tissue advances upwards more evenly and more rapidly, especially if it be accompanied by the formation of pus, the above process is so far modified that portions of the encrusting cartilage are lifted off as it were, and thrust into the joint in the form of flakes or worm-eaten plates. This exfoliation is not, on the whole, infrequent, the flakes looking comparatively normal, except on their under surface. All these varieties of destruction of cartilage may be met with in the same joint, one at one part of the surface, the other at another.

The *symptoms* of destruction of cartilage, apart from those of the joint diseases which usually lead to it, are few. Objectively we have in the degenerative form an unevenness of play of the surfaces one upon the other, or creaking at the same time. In the inflammatory forms as described, the painful condition of the whole joint will prevent any movement, unless the patient be anæsthetised, in which case the roughened condition of the surfaces may be made out by gentle flexion and extension, and perhaps by a little lateral movement. It is generally held, too, that when in the course of inflammation of joints the limb commences to start painfully and involuntarily, especially at night, ulceration of cartilage is present. The suffering produced by these startings is often great, and particularly as the patient is unable to control them. They do not commence until the destruction has gone so far as to bring the two bony surfaces nearly or quite into actual contact. The explanation of the phenomenon is probably this. Cartilage itself is not a sensitive tissue, though the underlying bone is so. When the former is ulcerated over two bones at their points of contact, the muscles ruling the joint will involuntarily do all in their power to prevent the inflamed bone surfaces from rubbing one on the other by fixing them in one position, simple contact of the diseased spots apparently producing no pain. When, however, the muscles become fatigued from time to time, or the patient is dropping off to sleep, the former relax a little, the diseased surfaces consequently move one upon the other, causing acute pain at the moment, and sudden reflex contraction again with aggravation of the suffering. This symptom does not accompany every kind of ulceration of cartilage. In the pyæmic affection of joints, for instance, where the encrusting cartilage is being uniformly and rapidly

removed, it is often absent. Nor is it a positive sign when present, its value depending much upon its association with other evidences of disease.

The treatment of ulceration of cartilage has nothing special about it, apart from that which would be suitable in an ordinary case of destructive synovitis of any kind or other.

AFFECTIONS OF THE BONES.

Turning now to those diseases of joints which commence in their bony constituents, and which are mostly of the inflammatory type, we find them less commonly the distinct result of simple local causes than the consequence of constitutional conditions such as scrofula, or those leading to *arthritis deformans*. Even when they have apparently started from injury, exposure, or other strictly local influence, it will usually be found that some constitutional taint has prepared the way for the changes that occur, or, in other words, rendered them particularly susceptible to inflammation. For a detailed description of the morbid changes in osseous structures the reader is referred to the essay on DISEASES OF THE BONES. We are only concerned with them here so far as they can be said to affect the functions of the joints. This they may do in several ways. On the one hand, they may extend directly into the latter, with or without suppuration, or, on the other, they may induce by their proximity a congestion of the remaining articular structures, with slow alteration of their structure. The first sequence is not often met with in simple osteitis of the articular ends of bones, such as follows injury or exposure. It is the more chronic affections depending upon constitutional states that are most to be feared in relation to the functions of the joints. Of the general states which have an effect upon the latter, it has been shown that gout and arthritis deformans probably only here affect the bones secondarily, and the same may be said of the more acute septic conditions of the system. In struma and syphilis the case is different, however. Here the course of the disease is not infrequently from the bone primarily to the other structures of the joint. Without going into details here, it may be briefly stated that the process is usually with each of these causes either sub-acute or chronic. Indeed it may be taken as a general rule that none of the acute affections of bone extend into the joint; they stop short at the epiphyses. Again, in both struma and syphilis the form which the bone affection takes is much the same in both cases. In each we find a hyperplasia of the medulla in the end of the bone leading to the formation of an abundant granulation-tissue. This may then either gradually expand into the joint, through the encrusting cartilage as described already (p. 350), or may undergo degeneration, and form osseous abscesses which make their way in the same direction; but this last is rare, for such fluid collections tend rather to present externally before implicating the articulation. When we come to examine into the question as to where this process begins, we find ourselves on interesting ground. We find, in fact, that (in struma at least) we are dealing with an inflammation at the epiphysary line of the bone in many, if not by far the greatest number of cases; we have, in fact, primarily an *epiphysitis* before us. This may or may not implicate the joint surfaces secondarily, and this depends greatly upon the structure of the articulation next the inflamed epiphysis. But the disease is so frequently mistaken for and treated as a true joint affection, and otherwise misunderstood, that a few words of special description of it may not be out of place here.

Premising that this is always a disease of early life, and remembering the amount of young vascular tissue undergoing developmental changes in the epiphyses and the activity of the processes involved, we are not surprised to find the physiological activity very often driven on into morbid excitement by a variety of causes. Thus, slight violence which would have no effect whatever upon the fully developed parts of a bone, may be quite sufficient to excite morbid hyperæmia in the delicate, almost embryonic tissue of the growing epiphyses. And the same may be said of exposure to extremes of heat and cold, &c. Again, those general morbid influences which operate from within find here conditions very favourable for their local development. Thus in certain septic states, just as we meet with inflammation in the growing

medulla of young bones, the well-known acute osteomyelitis, or in the deep vascular layer of the young periosteum leading to acute suppurative periostitis, so, in the analogue to the last tissue—namely, the growing line of the epiphysis—do we meet with inflammation, either alone or associated with one or both of the affections just named. The embryonic elements, here naturally proliferating as they are, require but little excess of stimulus to produce pus, and this stimulus is supplied over and above by the *materies morbi* of the septic state, whatever this be. The same may be said of struma, if it be true, as appears probable, that it is due to the presence of organisms in the blood (see p. 333). These passing through or actually lodging in the fine vessels of this line provoke a similar, less intense, but more permanent irritation. The syphilitic virus probably acts here in the same way and for the same reasons.

We have now before us in these some of the best known causes of acute epiphysitis and in struma and syphilis of the more sub-acute or chronic forms. But, in studying this condition more generally, it is almost impossible to avoid the conclusion that in that class of affections alluded to as sub-acute septic conditions (p. 337), epiphysitis will not unfrequently be found when more carefully looked for, just as the synovial affections are frequent here. It also appears not at all impossible that such sub-acute septic conditions may be inherited from the mother. Take dysentery; for example, which we know is often followed by joint affections in the adult, and note a remarkable case, recorded by Mr. Macnamara,¹ where disease during pregnancy after this disease in an otherwise healthy mother was followed by the birth of a very weakly child, who shortly after was found to be affected with extensive epiphysitis in several bones (syphilis or other disease was absolutely excluded in this case). This suggests, at all events, the thought whether septic conditions of the blood, often found with dysentery, may not be transmitted to the fetus in utero, and only produce actual structural changes after the infant has been embarked upon its own independent existence, and no longer supported by the vitality of the mother. If this be true, and there appears no reason why it should not be as reasonable as the hereditary transmission of struma and syphilis, it opens up a wide field for speculation as to the possibility of the inheritance of a variety of septic states from the mother, developing rapid disease within a short period after birth, not only in the bones, but elsewhere. It is possible that such a construction may be put upon the occurrence of the disease, in some of the cases in that extremely interesting series published by Mr. T. Smith,² of what he called 'Acute Arthritis of Infants.' Here the starting point of the morbid process was shown in almost every case to be the growing line of the bones of the joint. In some the disease was plainly pyæmic, while in others, for want of post-mortem examination of the viscera, we are left in doubt upon this point. Such pyæmic states no doubt frequently have their origin in the new bore, in putrid changes at the point of ligature of the umbilical cord; instances of this most pathologists are familiar with. But there are others in which septicæmia or pyæmia occurs with infants soon after birth in every degree of severity, and where post-mortem no trace of any source of infection about the cord or hepatic vessels can be discovered, or indeed in any part of the body. In such cases the possibility of inoculation before birth occurs to the mind. If, to take the same example again, dysenteric inflammation of the bowels, met with in the tropics, be due to the effort of the part to eliminate a poison circulating in the system, and if, as we know, joint affections frequently accompany this disease, and if it be shown by further observation that, as in Mr. Macnamara's case, a child born of a patient suffering from dysentery may exhibit evidences of blood-poisoning, it is not illogical to suppose that it may have contracted the septic conditions in utero just as it might contract syphilis or small-pox, as is believed possible by many.³ It will perhaps behove us then, in the future, in inquiring into the family history of such little patients as are brought to us with diseases about the lower ends of joints in very early life, to inquire just as carefully about any

¹ *Diseases of Bones and Joints*, 2nd ed. p. 85.

² *Bartholomew Hospital Reports*, 1874, p. 189.
Hutchinson's *Lectures at the Royal College of Surgeons*, 1881.

morbid states of the mother during gestation which could be traceable to sepsis, as we always do now about the possibility of syphilis or scrofula.

It is impossible to avoid these considerations, however hypothetical, in studying this question with the help of many published cases, and one's own observation, clinical and pathological, and in the light which is being daily thrown more and more clearly upon the possibilities of heredity. But, without carrying them further, we may now glance at the disease as we meet with it clinically.

Epiphysitis is met with in the acute, sub-acute, and chronic forms. Generally speaking, it is not found in healthy children whose vitality and family history are good; but in some cases where it exists the child's state in both respects has been inapproachable, for all we can find out. It must be admitted, therefore (at all events for the present), that it may be caused in some cases by external influences alone, such as blows, strains, exposure, &c. But it must equally be admitted that it can arise spontaneously quite independently of these, owing to causes operating from within in the form of constitutional disorders, such as syphilis, struma, and septicæmia. Some of these latter are beyond all doubt hereditary, such as syphilis and struma, others probably so in certain instances, such as some of the sub-acute septic conditions, if not the acute.

Acute epiphysitis is very frequent in early infancy. In 22 cases recorded by Mr. T. Smith, 8 occurred in the first month, 19 within the first six months, and 3 within the first year. Although frequently accounted for by a blow, squeeze, or strain, such as might occur during a difficult or instrumental delivery, very often there is no history of injury, and, in considering the cases carefully, we are tempted to suspect that in the majority of these acute affections we are dealing with a form of pyæmia or septicæmia independent of injury.

The disease is characterised by the rapid development of inflammation in the growing lines at the end of the diaphyses, sometimes within a few days of birth. This tends to run on rapidly to suppuration, the pus making its way either directly through the articular cartilage into the joint, or more frequently spreading over the whole growing plane, and separating the epiphysis from the diaphysis completely, finally bursting through the periosteum over the junction of shaft with epiphyses. Finally it may run up into the shaft more or less. When it passes off laterally alone and through the periosteum, it depends of course upon the anatomical relation of the epiphysary line to the capsule whether the pus shall make its way into the latter or not. In the hip, for instance, the joint is inevitably involved, while the knee may escape, the pus travelling outside of the capsule. When the joint is invaded by the pus, the result is usually a rapid solution of its cartilages, and in some cases of its bony constituents, to a greater or less extent. But in other cases the distended capsule bursts early, an abscess is formed in the soft parts, and opens externally, and after discharging for a time heals, and from the movements of the joint we are forced to the conclusion that its surfaces have not been damaged seriously. In those cases where in the first instance the pus travels into the soft parts quite clear of the joint, the latter may escape completely, but often it is secondarily involved at a later date. The rapidity with which abscesses form in connection with this disease is very remarkable. But the possibilities of repair after they have been drained are even more so. Occasionally when the disease has run its course, and the abscess has been opened, or burst externally and discharged, perhaps for weeks, the patient recovers, and has a very useful though shortened limb, with no trace of ankylosis, fair strength, and all its movements complete, or perhaps an increased mobility.

Just as in the syphilitic form of the affection we shall see presently the acute disease is most frequently found in those bones which add to their length most rapidly, and at the ends which contribute most to this, or, in other words, at those spots where physiological activity is usually greatest in bone. Thus among Mr. Smith's cases I find that, of those which proved fatal, out of 22 joints affected in thirteen infants, the hip was the seat of disease ten times, the knee five times, the shoulder four, the elbow, ankle, and sacro-iliac joints each once. Of those nine cases which lived, out of twelve joints affected there were five knees, three hips, two

elbows, one shoulder, and one ankle. This is only a rough estimate made from a limited number of cases, but is probably not far from correct.

Sub-acute and chronic epiphysitis is usually of strumous origin.

The first change noticed is usually a hyperæmia either of the nucleus of bone in the epiphysis or at the vascular line of union between the latter and the shaft. This is followed by proliferation of the medulla, which in the more acute cases forms pus, but in the usual chronic forms a quantity of granulation-tissue.¹

These inflammatory products now spread out in one or other of three directions, sometimes in all (unless, of course, recovery takes place). They may make their way outwards until they reach the periosteum, pushing it away from the end of the bone, and finally piercing it, to appear in the soft parts, if there be such. Or they may advance upwards, through the cartilage, in the way already described. Finally, they may extend into the shaft of the bone to a greater or less distance. The chief direction, however, for the inflammation to travel is laterally, along the plane of young tissue in which it originally commenced, and this it does generally. The joint proper is thus saved in many cases. But in other instances it is otherwise, *e.g.* the hip, where the epiphysary line lies inside the capsule. Here the inflammation of necessity reaches the joint surfaces in travelling along the plane of the epiphysis, and leads to more general disease. When the morbid process is extending in either the joint or shaft, on the other hand, it is usually a slower process.

In the last form of the disease (the *syphilitic*) to which it is necessary to make a brief allusion, we have somewhat an analogous process, usually sub-acute, to that taking place in struma. The disease has been studied by several observers in recent years, Wegner² being one of the first. His observations in some twelve cases have since been confirmed and amplified by Taylor,³ Parrot,⁴ Ranvier,⁵ and others abroad, while at home cases have been recorded by Howard⁶ and Goodhart.⁷ This disease may be the result of either hereditary syphilis, or that acquired within the first few years of childhood. It consists in an inflammation of the epiphysal lines, chiefly of the long bones, producing in many cases complete separation of the end from the shaft, as proved both during life and after death. This may be accompanied by the formation of abscess, with sinuses externally, or may run its whole course even to great swelling of the ends of the bones and separation with abscess, and yet be recovered from in a short time. The inflammation is regarded by Wegner as secondary to the calcification to a large extent of the epiphysary cartilage, due to the irritation of the syphilitic poison; such calcification going on faster than the usual vascularisation, the earthy matter eventually acting as a foreign body and so leading to inflammation.

Ranvier, on the other hand, and probably more correctly, regards the inflammation as primary in the growing line, and produced directly by the irritant of the syphilitic poison upon the growing vascular tissue.

One of the most remarkable points about this disease, like the acute form, is the power of complete repair of the parts affected, even after entire separation of the end of the bones. This is clearly shown to be possible by several of the recorded cases. But it is not the rule, little patients affected in this way usually dying before long of the syphilitic cachexia. The affection may then be taken as indicative of very extreme syphilitic intoxication.

Epiphysal disease of all kinds just as it lies in the most active tissue of the bones may be expected to be most frequent in those bones which add most rapidly to their length. And this is so. It is most frequent in the lower end of the femur, then in the lower end of the tibia and fibula and upper of femur; then in the lower extremity of radius and ulna, &c.

With these few general remarks upon epiphysitis, necessarily very brief, we leave the questions of symptoms, diagnosis and treatment of the affection for consideration in the section devoted to the special joints, where it will be considered in relation to the latter.

LOOSE CARTILAGES.

This is perhaps the most convenient place to consider briefly the general pathology of those *loose bodies* sometimes found in joints, usually called '*loose cartilages*,' by '*movable bodies*,' and by the Germans *Gelenkmäuse*.

The existence of these has been known as early as in Paré's time, who, in opening a dropsy of the knee, in 1553, found and removed a hard, loose, stony body, the patient recovering. The first to remove one designedly, however, appears to have been Pechlin (1601),¹ a Swede, who operated for this condition expressly on a young man of twenty.

These bodies are most frequently found in the knee, and after this in the elbow, less frequently in the hip, though I have met with them here post-mortem myself;² they are rare, though not unknown, in other joints. They may be single or present in large numbers, Morgagni having found twenty-five in a joint, but as many as 200 have also been met with (Volkman, *loc. cit.*) Pirrie mentions a case in which thirty-eight had been removed from the knee.³ They have been found to consist of the following substances, taken in the order of greatest frequency - fibrous tissue, fibro-cartilage, cartilage either pure or partly calcified or actually ossified, bone only, fatty tissue, fibrinous material, and fibro-cartilage surrounding a foreign body, *i.e.* the point of a needle. In size they vary from that of a pea to that of a small chestnut, and their shape is as variable, tending usually, however, towards the flattened oval. Their mode of production has been variously explained from time to time, but the theories now held with regard to this point may be classed briefly in two categories. They are supposed to be produced either by inflammation or by injury. Each of these causes, again, is supposed to act in two ways.

(a) Inflammation either throws out a quantity of fibrous material into the joint, which becomes consolidated, and, in the movements of the latter, moulded into pellets and nodules (Hunter), or (b) by exciting hyperplasia in the synovial tissues, leads to the proliferation of fibrous, cartilaginous, or bone-forming elements, normally present in the latter.⁴ A nodule being in the latter case formed in the loose tissue of the synovial membrane, is drawn upon hither and thither in the movements of joint, and thus elongates the villous fringe in which it is developed. Eventually becoming thus pendulous, it only needs some slight violence to tear it free, and send it wandering about the joint, and this whether the process have developed fibrous, cartilaginous, or osseous tissue.⁵ The irritant in this last case is believed now to be in many cases the same which leads to arthritis deformans. In the only case where, after death, I have met with such fringes bearing loose pedunculated nodules, the patient had advanced arthritis deformans of several of her joints, while the disease was only just commencing in that in which the loose body was found.⁶ That similar cartilaginous bony outgrowths may spring up at the border of the joint from the encrusting cartilage or periosteum, under the same stimulus, and from here become detached by movement, is also believed, but this is probably exceptional.

The traumatic origin is also twofold. Either (a) a part of the encrusting cartilage⁷ or of a meniscus⁸ is actually torn away by violence, and becomes partly or entirely

free to move about the joint or (b) a certain area of the encrusting cartilage, having been injured by concussion, a slow process of 'quiet necrosis,' as it was called by Sir J. Paget, takes place around the part struck, and without any suppuration the piece injured is shred off into the joint. This view, first put forward by Mr. Teale,¹ was supported by the observations of Klein² and Paget³ in cases which they have recorded (*loc. cit.*) In two of these, where death followed operation, the loose bodies, consisting of a layer of cartilage with a plate of bone on one aspect, were found to fit accurately into a corresponding depression on a condyle of the femur, and there was a distinct history of injury in all. Mr. Barwell, too,⁴ records cases of traumatic origin, probably in this sense also.

Finally, a case is recorded⁵ in which the point of a needle was found as a nucleus of one of these bodies after its removal by operation. This had probably been the **2** instant in this case which had initiated the hyperplasia of the synovial tissues. Again, blood-clots are supposed to give rise on hardening to loose bodies.

The symptoms to which these latter give rise are usually distressing and unmistakable, if only one or two bodies be present. When greater numbers exist, they are less liable to produce trouble, though they can be felt very easily. When single, the first symptom is usually agonising pain during some unusual movement of the joint, in the vast majority of cases of the knee, to which this description refers. This pain is sudden, rending, and often produces faintness, and with it the limb is observed to be fixed in the flexed position immovably. This fixation generally lasts from a few hours to a day or two, and then gradually yields, the joint regaining its normal powers soon after. Such an attack is generally followed by a mild synovitis with effusion. When the latter has been absorbed, the loose body may usually be found at one or other aspect of the joint, but most frequently in the pouch over the external condyle. The pain is then explained easily, when we remember that, if such a body catch either between the ends of the bones or under a ligament, and an attempt be made to straighten the limb as in walking, the ligaments must be at once subjected to the most enormous stretching force, owing to the length of leverage and the shortness between the fulcrum and the resistance.

Such attacks are liable to recur with ever-increasing frequency so long as such a body remains in a joint, and the patient lives in constant apprehension of their occurrence, having often no means of guarding against them, and being unable to say when they will occur. Sometimes a bandage or strapping, by retaining the body in one of the pouches, may prevent such an attack for a time; but its action is always uncertain, and sooner or later the patient will call urgently for an operation for their removal. This will consist either in *direct* excision of the offending body at once, or, as recommended by Syme and Goyrand, in first dividing the capsular structures over it subcutaneously, and allowing it thus to slip out of the joint under the skin to be removed from this some days later when the capsular wound has closed (*indirect* method). In those cases, however, where a loose body is felt in a joint, but gives little trouble, no operation for its removal should be undertaken; for, although the advance of surgery in late years in the direction of antiseptic treatment of wounds has brought with it a great diminution of risk in the operation called for here, yet the procedure must still be regarded as more or less dangerous, and from time to time, with all antiseptic precautions, joints are destroyed, as I have seen in one case operated on by a most skilful surgeon, and by the most approved methods. In such mild cases, if the body can be coaxed into a favourable position, it may be retained sometimes long enough, by a pad with a hole in it, to produce a slight adhesion, which will prevent its slipping about for a time.⁶ But such adhesions usually break down sooner or later, if they ever exist, and the patient is as bad as before. It is for these reasons that the excision operations, direct or indirect, are called for eventually in many cases. As to the actual dangers of the latter, they have by no means been

⁶ Manby, *Birmingham Med. Review*, 1875, p. 158.

exaggerated in former years. Various collections of cases have been made and tabulated, and even admitting that those taken from general literature contain their just proportion of unsuccessful cases, which is extremely unlikely, still the mortality is shown by them to be very high. Thus Volkmann,¹ among 179 cases operated on by both methods, which he had collected, found 38 deaths. Berthenson,² quoted by him, among 162 found 20 fatal, and H. Larrey³ among 131 operations by the direct method gives 98 recoveries, 28 deaths, and 5 failures. Volkmann (*loc.*), although he does not state how many of his collection were direct and how many indirect operations, states that the percentage of deaths in his list was nearly the same as in Larrey's—namely, 21·3. This is probably nearer the truth than what we gather from Berthenson's list. The largest collection of these cases, however, which has yet been made—namely, that very careful one compiled by Benndorff⁴ in 1867—shows a somewhat lower mortality. Among 218 direct operations, he found 41 fatal cases, or about 18 per cent.

The mortality after the indirect method is not so high, yet in Larrey's list it stands at 12·8 and in Benndorff's at 9·9.

These figures, although placing the mortality for both operations probably far lower than it in reality is, show that, at all events, some years ago they were both formidable procedures.

But an improvement has taken place since then. Thus Mr. Barwell,⁵ from a very carefully compiled list, including all the cases he could collect as occurring between the years 1860-75, finds the mortality after the direct method fallen to 8·4, and after the indirect to 2·5.

And it is probable that, if all the cases operated on during the last five years could be collected and tabulated, we should find a still greater improvement. When Volkmann made his collection of 179 cases of excision of loose bodies from the knee some years ago, and found among them 38 fatal, he little thought that in 1881 he would be able to say that he had himself opened, drained, and washed out non-suppurating knee-joints more than 200 times without one bad result.⁶ The results, too, of operations on the knee for *genu valgum* lead us to hope that the great dangers of opening the joint have been almost done away with by the late advances in antiseptic surgery, and that removal of loose cartilages from the joint will be equally free from great risk. If this be so, it will not be so necessary to inquire into the relative value of the direct and indirect methods. Hitherto there has been a good deal of difference of opinion on this point. On the one hand, it has been argued from the statistics of the two operations, that the danger of the indirect was much less than the direct, while on the other a strong objection to the first method was raised on the grounds that it was frequently found impossible to carry it out, owing either to the attachment of the loose body by a pedicle, which prevented its protrusion through a simple slit in the capsule made subcutaneously, or to the difficulty of clearing a space for it in the subcutaneous tissue ample enough to admit of its lying quietly without any tendency to slip back into the joint. Thus, though in Larrey's table there were only 12·8 per cent. of deaths after the indirect method, there was 38·4 per cent. of failures, and, correspondingly, 9·9 and 23·5 per cent. in Benndorff's list. Again, in Mr. Barwell's table, though the deaths have sunk to 2·5 with the indirect method, the failures are still as high as 25 per cent. Even in Squarc's⁷ experience, who may be said to have perfected the indirect method, though he had no loss of life, yet he had four failures in fourteen operations. It is impossible, however, for the present, to state from statistics what the inherent dangers of these procedures really amount to, and what their relative danger. It will only be possible to do this when larger series of cases are accurately recorded by individual operators operating with the same precautions as to cleanliness, &c., and by the same rules, which can be added up or contrasted with our full

¹ *Pitha-Billroth's Handb. der speciel. Chir.* Bd. II. Abth. 2. ² *Ibid.* ³ *Ibid.*

⁷ Quoted by Barwell, *loc. cit.* p. 282.

confidence that they embody their entire experience of the operations in question. Cases taken here and there, occurring at different times and in the hands of different surgeons, cannot fairly be contrasted or taken in the aggregate to prove anything positively. In the meantime the tendency of opinion appears generally to be strongly in favour of the direct method conducted with the strictest antiseptic precautions. Those who operate in this way now-a-days have little fear of serious complications. Thus Mr. Barwell says, 'I have excised a large number of loose cartilages, and have never experienced a failure or an untoward event.' Dr. Iverson¹ of Copenhagen, too, in urging this method with strict antiseptics, even so long ago as 1874, gives thirteen operations with only one death. Probably much better statistics could be shown to-day by the same author. Still there are those who look upon the simpler methods of bandaging and rest as a means of procuring adhesion of the loose bodies as adequate treatment for many cases, and adduce cases in support of their opinion.²

As to the modes of excision themselves, they may be very shortly described. The direct consists in simply drawing the skin tightly over the loose body (which is firmly fixed by an assistant at the most convenient part of the joint) and making an incision right down upon it. This being done, it will sometimes suddenly start out through the opening of the capsule, and get free. In other cases where it is attached by a pedicle, it is necessary to draw upon it with forceps, and either tear or cut through the latter. The wound being dressed antiseptically is allowed to come together, and the limb is immobilised securely in one way or other, and left so for some days until union has commenced, when it may be inspected and put up as before until quite healed. The indirect method consists in passing a broad-bladed tenotome under the skin at some little distance from the loose body, fixed firmly by an assistant. With this a subcutaneous bed is prepared for the reception of the foreign substance, by making sweeps with the knife through the areolar tissue. When room enough has been made, the capsule is incised by cutting upon the loose body, which now slips out into its bed freely, if not pedunculated. If attached, it may not slip out, or having done so may return, when the direct method must be tried. When it has been brought into its subcutaneous bed, a pad is put over the point corresponding to the capsular incision and secured there until this is healed, the outer wound being left free for any drainage that may be necessary. A number of other methods now abandoned have been in use from time to time, but need not be discussed here.

Finally, it may be noted before concluding this subject, that resection of joints has been proposed and actually practised on account of the presence of loose bodies. Thus Hueter³ states that, in a case where the elbow contained several loose bodies which interfered greatly with its functions, he was led to conclude that a resection offered the best prospect of a useful arm. He therefore performed the operation with the best result. Similarly in the case of the ankle-joint in which a patient had been crippled for some years by a loose body, he dealt in the same way with it with a very satisfactory result.

ANCHYLOSIS.

Having now considered generally the destructive processes in the soft tissues and bones of which joints are made up, it is necessary to bestow a little attention upon the reparative processes found here.

After any form of inflammation of a joint, non-destructive or destructive, which has been recovered from, plastic material will be found in or about the articulation almost certainly. This will vary in quantity from a few flakes of lymph floating in the synovium to the masses of fibrous tissue or bone found in cases of firm ankylosis.

Lymph floating about in the cavity is usually soon absorbed when the joint is put to use once more, but sometimes it becomes moulded into those loose bodies already described (p. 355). When in greater amount, so that it forms a thin layer over the still healthy cartilages and synovial reduplications, it may remain in a more or less soft state, or become organised into a material resembling embryonic fibrous tissue. In

¹ *Brit. and For. Med.-Chir. Rev.* July, 1874. Quoted by Manby.

² Manby, *Birmingham Med. Rev.* 1875, p. 158.

³ *Gelenkrankh.* vol. i. p. 265.

either of these conditions, after disappearance of the inflammation, it produces a good deal of stiffness in and about the joint, which the patient is therefore unable to flex voluntarily. If, however, forcible flexion under an anæsthetic be made, there is no difficulty whatever in tearing through the new material, whether now vascularised or not, and in restoring at all events the passive mobility of the part. As a rule, if this be done once or twice, the plastic exudation is torn and rubbed sufficiently to destroy its continuity, and the patient is able after a few days of pain, and perhaps a little swelling, to use the joint again, after which the remains of the new material are soon disintegrated and absorbed and the part regains its usual mobility.

But a very different condition results if the cartilages have been destroyed by an inflammation. When the destructive process ceases in this case (in which there is usually an external opening into the joint at one or other aspect), a quantity of the products of inflammation remain between the ends of the bones in the form of a fine-celled vascular granulation-tissue. This is now organised, the cells becoming first

FIG. 70. Section of a Knee-joint, the bones of which are united by ligamentous tissue after scrofulous disease. (From a preparation in the Museum of St George's Hospital.)

FIG. 71. Section of a Hip, presenting complete Bony Anchylosis of the Ilium and Femur. (From a preparation in the Museum of St George's Hospital.)

form and eventually filamentous, and arranging themselves in bundles in the direction of the small vessels developed in the material, until finally the latter is converted into firm fibrous tissue. Through this the ends of the bone may now be firmly soldered together beyond all hope of recovery of the movement of the joints, and fibrous ankylosis be produced (fig. 70). Any attempt to tear through adhesions of this kind forcibly under chloroform might possibly be successful, but would be followed by such an amount of inflammatory reaction as would only again unite the surfaces as before, if it did not lead to actual suppuration.

Again, if the cartilage be all destroyed and the bones come into contact, more or less arrest of the destructive action is usually followed by a much more elaborate reparative process. Here the inflammatory material between the softened ends becomes organised as before; but the change goes a step further, and osseous matter is deposited in the embryonic fibrous tissue, just as in the case of a fracture it is deposited in the analogous plastic material called 'definitive callus,' until the whole or part is converted into true bone (fig. 71). This *osseous ankylosis* is usually very firm, and cannot be broken down. The arrangement of the new trabeculae is very irregular,

but otherwise the uniting medium differs in no degree from ordinary bone. In many cases the medium of union between the ends of a joint recovering after destructive inflammation, whether of the whole or part of the cartilage, is partly fibrous and partly osseous. Again, in those cases of rarefying osteitis of the ends of bones, in which the surfaces of the joints are invaded by the spongy granulating medulla without suppuration, it is simply a question of the inflamed medulla of the two affected bones coalescing and becoming fused into one mass of spongy material. If repair now set in, we have the same organisation of this mass into fibrous and eventually osseous tissue as that mentioned above, and the most perfect example of bony ankylosis results that can be met with. Here, too, the process is precisely analogous to that taking place in the repair of fractures, a 'simple' process in this case where there has been no suppuration and no external wound. It may be added that in inflammation of joints every shade of fixation, from that due to the mere effusion of a little fibrinous material between the articular surfaces, or the planes of the tendinous structures around, to that complete fusion of the ends of the bones just described, may be met with in different cases. The diagnosis of the particular condition present in any given case will be based upon the total of the clinical history from the beginning.

NERVOUS OR HYSTERICAL AFFECTIONS.

Any essay on joint diseases would be incomplete which did not take into consideration those cases familiar to most surgeons, in which one or more of the symptoms (subjective or objective) of a diseased articulation are complained of, but where careful examination fails to detect any evidence of structural change, where there is in short a 'mimicry' of the different joint affections without any local disease.

The subject must be very briefly dealt with here. It will be found treated of specially and very ably by Sir J. Paget in his '*Clin. Lectures*,'¹ and also by Jolly indirectly in his essay on '*Hysteria*.'²

This *neuromimesis* of joint affections is characterised, as a rule, by the onset of severe pain in some articulation which, from the patient's description, is at first sight remarkably like that accompanying one or other of the diseases of the part. The patient may complain at the same time of some of the other subjective phenomena of true disease, such as a sense of heat and tenderness on pressure or starting of the limb. The resemblance may be further heightened in a few cases by slight swelling, or, more frequently, by deformity; the limb assuming the position commonly observed in disease. All this may be before us in any given case, and yet no evidence of true structural change in the joint be present to the most careful and skilful examination.

Such cases are of frequent occurrence, especially among the higher classes, of whom Sir B. Brodie says, 'that at least four-fifths of the female patients who are commonly supposed to labour under diseases of the joints, labour under hysteria and nothing else.' But among the less favoured classes they are by no means uncommon. It is, therefore, most important that the whole question of *neuromimesis* should be carefully studied; firstly, because we might otherwise easily be misled into a diagnosis of local disease where none exists—and it should be remembered that not very long ago, when these conditions were less studied, serious operations, and even amputations, were undertaken in cases where local disease was suspected, but where the part removed was found perfectly healthy—and secondly because, if we accepted such statements as those of Sir B. Brodie too lightly, we might fall into the almost equally unfortunate error of overlooking real disease at a stage when it was most within the reach of well-directed treatment.

Neuromimesis is met with at almost any period of life from infancy (Smith, *l.c.*) to advanced age (Paget, *l.c.* p. 194). It is, however, most common in the decade which follows puberty (Jolly, Paget). It is much more frequent among females than males, though by no means rare with the latter. All classes suffer, but the wealthy more than the poorer. In either it is met with among those disposed to functional

disorders of the nervous system, or belonging to that habit commonly spoken of as neurotic, using the term in its ordinary signification. Of the abnormal condition of the nervous system which gives rise to the neuroses, little or nothing is known. We only know from a general study of its symptoms that it can be transmitted hereditarily or acquired, partly by sensory irritation, and partly from the effects of an abnormal state of the blood. It develops itself most powerfully where both these influences combine. It will be well then, in any case in which we suspect the condition before us to be one of 'nervous mimicry,' before examining it in relation to the various symptoms which we look for in real disease, to consider the following questions relating to the patient's general history.

1. Has there been insanity, epilepsy, paralysis, eccentricity, or strong emotional disposition manifested among the sufferers' relations of the preceding generation? Were their parents aged at the birth of the patients?

2. Have the latter been subjected to any great emotional disturbance, chronic or acute? *e.g.* such as that of fright, jealousy, disappointment from failure in life, or mortification due to real, imputed, or supposed dishonour. Have they lately gone through excessive mental exertion or borne the strain of night-watching, especially where the affections have been engaged? During the strain there is little liability to attack, but when this has relaxed, and the stimulus of excitement is gone, the patient yields.

3. Have they lately gone through any physical over exertion of an unusual kind, prolonged or brief, or been subjected to privations? Has there been any over-stimulation of the generative organs, due to masturbation or the like. Are they anæmic, or suffering from any of the chronic affections of the generative organs? The very grave diseases of these parts, such as cancer, have little significance here.

4. Finally, if constitutionally neurotic, have they been in a position to see others suffering from those affections with which they believe themselves to be afflicted; in such a position, in short, as to call forth the involuntary imitation?

Answers to these questions will furnish us with evidence as to causes hereditary, mental and physical, engendering the general neurotic state, and also that particular phase of it manifested in imitation of morbid phenomena.

Turning, then, more particularly to the latter, as exhibited in the joints, it will be found most convenient to examine in each case how far the symptoms complained of are consistent as compared with those present in true disease.

The affections of the joints most frequently imitated are the more or less acute inflammatory, whether simple or strumous; the gouty and rheumatic less often. Any of the subjective symptoms of these, and some of the objective, may have to be considered in mimic cases, whether pain, tenderness, heat, throbbing, stiffness, deformity, swelling, or wasting.

Taking the first of these *pain*—it may be first broadly stated that in cases of mimicry it is complained of as severe out of all proportion to anything subjective or objective said or found to be the matter with the joint. The patient usually represents it as extremely severe, and yet, when engaged in conversation or otherwise diverted, is palpably but little affected by it. It is moreover generally referred to the more superficial parts of the joint. If asserted to be increased by movement, an inconsistency is soon apparent in the exaggeration of the symptom. That gnawing burning pain complained of by those who are suffering from ulceration of cartilage and slow disorganisation of a joint is also mimicked; but, in that case, the objective symptoms, such as heat, swelling, œdema, &c. are absent, and under chloroform the movements of the joint will be found free and unaccompanied by any sensation of friction. Sir J. Paget suggests as a sign that pain is due to real disease; that, if chloroform be given, the joint returns to rigidity immediately on the first dawn of sensibility as the narcotic passes off; while in neuromimesis the joint is only again rendered stiff when the patient has become fully conscious of all his surroundings and condition.

The temperature of the affected part must be very carefully studied, for here lies one of the greatest aids to a correct diagnosis. In the first place, it should be noticed whether the joints on both sides have had an equal external covering for some time before

our examination. If one have had only the usual clothing, and the painful one have been swathed in dressings or bandages, the former may be much cooler than its fellow, and without care we may thus be misled. But, if both have been uncovered for a considerable time, and subject to the same external conditions, it will be usually found that in mimic cases the temperature of the painful joint is no way affected, or, if slightly increased, that the pain complained of is out of all proportion to the increase. The affected joint, on the other hand, may be, and often is, even cooler than its healthy fellow, which is strong evidence against disease. In true inflammatory disease there will in most cases be a sufficiently marked elevation of temperature to indicate the condition. The rise may be estimated by the palm of the hand, if the latter have been, as it were, trained to such work for a long time, and if a careful comparison be made between the limbs of both sides, and the surface of the rest of the body. In doubtful cases, the surface thermometer may be useful, if used with due care. The fact that with real disease one part alone of a joint may be hotter than another should be remembered, for this could not be the case with pure neuromimesis. Flushings and transient rises of temperature alternating with periods of normal heat in a joint do not indicate local disease. If this were present, the part should be constantly overwarm. Patients will sometimes complain that, though the part is cold during the day, it is hot and burning at night. If gout be not present here, it is most likely a case of neuromimesis. This diagnosis will be strengthened if the part during the day is cold, and generally of a purplish mottled appearance.

In cases where very severe pain is complained of, with possibly other objective signs of local mischief, the absence of any general rise of temperature of the body may also help the diagnosis. For with true disease bad enough to produce very acute pain, deformity, &c., there would probably be some general disturbance too. But frequent observations must be made of the temperature of the suspected joint, and of the whole body, and the information thus obtained be taken with all the other evidence, otherwise error is likely to arise.

The tenderness complained of as very great, on the slightest touch of the joint, is also to be suspected if it be accompanied by neither heat, swelling, nor redness. It will usually be found, in such cases, that, if the patient's attention be diverted, the part may be very freely handled without complaint, but that when a question is again put concerning the joint, the slightest touch is exclaimed against. This tenderness is usually felt only in the superficial parts, deeper pressure producing no increase.

Of stiffness and deformity, it should first be noticed that, if very acute suffering be complained of in a joint, lasting for weeks, and the part remain extended and movable, it is highly improbable there is any local disease present, unless it be rheumatic or gouty.

Sometimes, however, in cases of neuromimesis, the joint may assume a position usual with real disease. Thus the hip may be flexed, adducted and inverted, and thus fixed, great pain being complained of on attempts to straighten it. But here the absence of all heat, swelling, redness, or general fever, always present where in real disease the limb has recently assumed this position, will probably guide us to a right conclusion, together with the history of the case, hereditary and personal. In such instances, too, the limb may be often involuntarily or passively relaxed, without any movement of the pelvis, if the patient's attention be closely engaged on something else, which could never occur with real disease. It should also be noted that, where mimic disease has been accompanied by an unusual position of the joint for long periods, even for years, no true deformity of the part has been found after death. This is not the case where true disease has been present—where, for instance, more or less alteration of the surfaces of the bones is usually found, with or without sub-luxation in greater or less degree.

As to swelling, it may be said never to accompany the simple mimic affections. It may, however, have been caused (where the latter have been mistaken for true local disease) by stimulating outward applications, the effects of which last often for a considerable time.

Wasting, in the true sense of the term, is not met with in mimic disease. That

rapid loss of tissue observed about a joint truly diseased is never seen here. Disuse (if the other limb be still used) may produce leanness on the painful side as compared with the opposite; prolonged and firm bandaging may do the same, or the wearing of elastic coverings; but the loss of bulk is usually but trifling, and in clear contrast to what might be expected were disease present in a degree equal to the patient's belief, or in correspondence to other symptoms.

It is only by the careful consideration of all these subjective and objective symptoms, together with the patient's family and personal history, that we can safely come to a diagnosis in this very important class of cases. For further observations on this subject the reader is referred to the essay on HYSTERIA.

AFFECTIONS OF THE HIP.

The joint which claims our attention first is the hip; not only on account of its size and importance, but also because it is one of the commonest seats of articular disease. We shall consider the latter as met with here in the order already followed in the section of this article devoted to general pathology.

Simple acute synovitis is not as commonly met with in the hip as in other joints, owing to the great depth of the soft tissues which protect it from external influences.

The pathology of synovitis having been already discussed (p. 334), we need only add as regards this particular joint, that here it is usually the result of over-exertion and exposure combined acting on constitutions not robust.

The subjective symptoms observed are stiffness and heat at first, soon succeeded by throbbing and pain, not only in the joint itself, but also in the knee, though the latter be perfectly sound—a fact explained by the connection between the two joints through the obturator nerve. Thus pain is much aggravated by movement or pressure over the joint in front and behind, and causes limping very early, and later prevents walking altogether.

Objectively we find swelling in two situations—viz. over the front and back part of the joint where the tenderness is most felt, and where fluctuation may be occasionally discovered. The next most striking symptom is the position of the limb. If the patient be young, and the inflammation recent, the latter will be markedly flexed, abducted, and somewhat everted (fig. 72). This position is brought about as follows. The synovial membrane and overlying capsular structures are now inflamed, swollen, and tender. That portion of the capsule normally tense in the straight position of the limb—viz. the anterior incorporated with the ileo-femoral or Y-ligament—is, as we might expect, the most in need of relaxation. The patient, therefore, flexes the thigh involuntarily to relax the tension which adds to its tenderness. The inner limb of the Y-ligament and horizontal posterior fibres too are relaxed for the same reason by eversion, and the outer part of the Y and upper part of the capsule by abduction. In short, the joint is placed involuntarily in the position most calculated to adequately relieve the various strong parts of the irritated and swollen synovial and capsular structures (fig. 72). In this position it is fixed by muscular action, lest any rubbing of the sore surfaces should take place; and all attempts to move the limb are resisted strongly, the only change admitted of being that of the pelvis, which now moves as a whole with the thigh. In standing the patient will now be obliged to lower the pelvis on the affected side to make up for the shortening due to flexion and abduction of the limb, and admit of the foot resting on the ground. But when in bed he will probably lie on the affected side more or less in order to have the support of the bed for the now flexed and abducted limb, whose every movement is painful. If asked to lie on the back, he will object if his case be acute on account of pain; but if persuaded the limb will maintain its characteristic position. Any attempt now to bring it parallel with its fellow results only in movement of the whole pelvis, the angles between it and the axis of the limb remaining fixed. Thus abduction into parallelism can only be effected by lowering the pelvis on the diseased side. This will of course bring the limb below its fellow, so that it now looks longer than the latter, as it lies in contact with it. At

the same time the knee can only be brought down to the bed by rotation downwards and forwards of the pelvis on its transverse axis, accompanied by great increase of the lumbar curve of the spine (see fig. 75, p. 370). The greater the flexion of the thigh on the pelvis, the greater this lordosis. This characteristic position of the hip-joint with early synovitis is well seen in fig. 72, copied from a photograph of a child's body into whose hip-joint I had forcibly injected water by means of a syringe with a screw piston, after rigor mortis had passed off, thus repeating an experiment made long ago by Bonnet. As the fluid was slowly

FIG. 72.—From a photograph of the body of a child into whose right hip-joint I had injected water, while the body was suspended from the arms after rigor mortis had passed off. While the water was being forced in through the pectineal eminence of the pubic bone, by means of a screw piston, the right limb rose slowly and easily into the position in which it was photographed (namely flexion, abduction and eversion), and remained so without any support until the photograph was taken, not altering its position in the least until later, when the water was allowed to escape from the joint, when it at once fell to its normal position. How far it deviated from this during injection will be seen if a line be drawn down the centre of the body through the ensiform cartilage, umbilicus and symphysis pubis in the left-hand figure.

forced in through a hole bored through the ilio-pectineal eminence of the pubic bone—the body being suspended by the arms—the limb gradually rose without the slightest assistance into the position shown in the engraving. Thus it remained until the water was allowed to run out, when it slowly sank down beside its fellow. This experiment illustrates without any dissection what parts of the capsule of the hip are most tense and unyielding, and which are the reverse. And this, on the other hand, indicates what parts require most to be relaxed when in an inflamed, swollen, and tender condition. The theory of muscular contraction, the result of reflex irritation through the nerves supplying the hip-joint, is thus shown to be unnecessary.

The general treatment of this synovitis of the hip will be that sketched already (p. 335). The only special points to be noticed here, as regards the hip, are the modes of fixing the joint so as to give it complete rest. If the case be severe enough to require more than a few days' rest in bed, with free leeching and hot fomentations, the question here arises: in what position should it be immobilised—as it is, flexed, abducted and everted? or, brought down forcibly as nearly to a straight line as possible? Hitherto it has been almost universally held that the limb should be straightened rapidly, if necessary forcibly, under the influence of chloroform, and so fixed by some

appliance; and the general practice has been in accordance with this view. But of recent years the opinion has been gaining ground, that perhaps what is gained by at once straightening the part, and so the easier fixing it and preventing deformity subsequently, may be lost by bringing the joint at once into a position which is clearly *not* that of greatest rest, seeing that it was the desire to obtain the greatest relaxation of the inflamed structures which led the patient involuntarily to flex, abduct and evert the limb in the first instance. And practice has of late been modified by this view. Formerly the treatment followed in these cases was to give the patient chloroform, and then forcibly bring down the limb, fastening it thus to a long splint running from the axilla to below the external ankle. From this splint extension was made by a collar or strapping running from the ankle to the forked lower end of the splint, while counter-extension was made by a perineal band reaching to the upper end, which was pierced to receive the ends of the latter. Or, the straightened limb was put up in a plaster of Paris or starched bandage. The latter had the disadvantage of interfering more or less with the use of local antiphlogistics, and for this reason were not used as much as Liston's long splint. Of late years the treatment with many has been rather to bring the limb parallel to its fellow, slowly and gradually, so as to disturb the involuntary adjustment of the inflamed ligaments as gently as possible. This is usually effected by one or other form of gradual extension with a weight—that is, either the weight is made to pull at once in a direction parallel to the sound limb, or, as Mr. Marsh¹ proposes, is so contrived as at first to exert its force in the direction of the affected thigh, and then gradually change into the more direct pull downwards. If the first of these methods is chosen, it is best carried out by means of strips of sticking plaster running down each side of the leg, and fixed thus to the latter by a turn or two of plaster and a bandage. The ends coming below the heel are fastened to a cord, which passes over a pulley at the end of the bed, and is attached to a weight of one pound and upwards. The plaster is kept from pressing upon and chafing the ankle by the insertion between the strips of a small piece of flat wood, which keeps them apart. With this appliance the limb may in many cases be brought down to a straight line, in a comparatively short time, and without any violence to the joint. It has the disadvantage with children that they are apt to evade the steady pull of the weight by twisting the body until the limb, and not the body, lies in the direction of the pull from the weight. This difficulty may to some degree be met by arranging sandbags at either side of the child's body, or by using a perineal band fastened to the head of the bed. Or, if there be any tendency for the child to slip down to the end of the bed, the foot of the latter may be raised a few inches from the floor, when the weight of the patient will be the counter-extending force. Mr. Marsh's mode of extension is to begin by placing the pulley high enough over the bed to lie in the axis of the thigh as the patient rests on his back. If the pull is made in this direction for a short time, it is found that the limb has come somewhat down. The pulley is now shifted a little nearer to the foot of the bed, and the extension made thus a little more directly downwards. In this way by degrees the position of the part is restored before long.

Extension, however practised, is usually comforting to the patient when once applied. It steadies the joint, and counteracts the action of the muscles. If the case be one of very acute synovitis, it may be necessary to use an anæsthetic for the application of the plaster and arrangement of the child in bed; but once this is completed, but little suffering will be noticed.

But other appliances besides this extension may be employed to keep the joint at rest, and at the same time to bring down the limb gradually. One of these is Thomas's splint, which is as useful in these simple acute cases as in those more chronic, to be alluded to presently. As this splint is in more general use for the latter, its construction and application will be considered with them. It is particularly useful in the later stages of the affection, as it enables the patient to get about in the fresh air, when otherwise debilitating confinement might be necessary.

¹ *Brit. Med. Journ.*, July, 1876.

Acute suppurative synovitis of the hip is so rarely met with in the simple form produced by external influences, that its consideration may be left over until we are studying the diseases produced by constitutional causes, where it will often be found.

The *simple sub-acute and chronic* forms, too, although doubtless quite distinct as to causation, are so like in history and effects, and in the necessary treatment to those affections induced by the so-called strumous diathesis, that they need no description for themselves here; enough will be said of them practically in discussing the latter.

The synovitis of the hip produced by those diseases we have grouped together under the common head of *pyæmic or septic* (p. 337) may be either acute, sub-acute, or more rarely, chronic.

In the first instance the symptoms (p. 337) develop very rapidly, and the limb quickly assumes the characteristic position of acute synovitis described above (p. 364). ~~It~~ this soon becomes modified, as a rule, in bad cases. The flexion is the same, or even increased; but eversion and abduction soon give way to inversion and adduction, for the following reason. This acute septic synovitis, usually of the suppurative form, is essentially a destructive inflammation; it leads rapidly to more or less softening of all the capsular structures by the contact of its irritating products, now distending the latter, and primarily leading to the assumption of the first position described, all their fibres being now equally on the stretch. As the inflamed capsule then commences to soften, its weakest part yields first, *i.e.* the posterior inferior. This now admits of more flexion still, for the greater relaxation of the strong anterior fibres. The horizontal posterior fibres, which in the distended condition of the capsule help in the eversion, are the next to stretch, admitting of inversion, which is now the more possible as the Y is relaxed by flexion, and its inner limb has no strain to be taken off by eversion. Finally, the upper and outer anterior fibres yield, and adduction then takes place. All this time the muscles are involuntarily placing the limb in the best position for relieving each remaining part of the capsular structures of tension, and thus fix it at last at flexion, adduction and inversion. The flexion in these cases is sometimes extreme, the knee rising occasionally nearly to the umbilicus. If this be so, the head of the femur will lie nearly out of the acetabulum, below and behind, resting in great part upon the softening capsule. If the latter now give way at its weakest part, which is just there, and the ligamentum teres have been equally softened, the least jerk, even of a patient moving in bed, is sufficient to dislocate the head of the bone out of the acetabulum on to the dorsum ilii. Some time ago a striking case where this 'dislocation by distension' of Volkmann had occurred, came under my care at University College Hospital. During typhoid fever rapid effusion took place into the hip-joint of a hitherto healthy ploughboy; the limb soon became acutely flexed and adducted, and by some movement unknown to those about him, the femur became dislocated as he lay in bed. The appearance was typical, and the shortening extreme. Six weeks later, during convalescence, I reduced the dislocation by manipulation under chloroform and without difficulty, and found the surfaces of the articulation apparently quite healthy on moving the joint. This movement of the bone, however, caused the head of the bone to slip out again immediately. I replaced it once more on the spot easily, and so retained it, the boy making a complete recovery. Several months later he returned from the country to show himself, when I found the limb of normal length, straight, and, with the exception of stiffness about the joint, quite as the other. In this case the strong resistance of the anterior structures of the joint, apparent when the dislocation was reduced, in the flexed position of the limb, was not overcome forcibly while the patient was under the anæsthetic, but was treated by gradual extension, lest the remains of the capsule should be injured. The result showed that they stretched in the course of a few days, while retaining the head perfectly *in situ*. There was no evidence of abscess from beginning to end of case.

Acute septic synovitis of the hip should be treated on the general principles already alluded to (p. 339). But here it will probably be better to prevent the flexion, adduction, and inversion from the first, if possible, by extension or other methods, rather than let the limb have its own way of relieving itself and trust to extension later on.

For here the process is so rapid that dislocation may occur very early, as described, while simple extension with a small weight would prevent this, besides keeping the part at rest. As long as the first position remains one of flexion, abduction, and eversion, there is no fear of dislocation, and the case may be treated with the ordinary local and constitutional antiphlogistics, with rest in bed. But as soon as adduction and inversion are commencing, extension is called for. Later on, if the case be only then seen for the first time, extension will be called for in either case, unless dislocation have already occurred, when it could do no good without previous reduction.

If in the early stages of this affection distension of the joint be very apparent, with fulness and fluctuation, in front and posteriorly, the effusion, which may be serous or purulent, should be at once aspirated from behind. This operation may be repeated several times at short intervals, if required. But, if this should fail to check the rapid advance of the process, it is best to make a free incision into the capsule from behind, and insert a drain-tube. The incision here should be parallel to the posterior border of the great trochanter and about from an inch to an inch and a half distant from it. Here the capsule is easily reached, opened, and drained. If complete disorganisation of the joint should be found at the time or should supervene, the incision can easily be prolonged and converted into one suitable for excision (see EXCISIONS). During the whole operation the strictest cleanliness should be observed, one or other of the antiseptic dressings being subsequently used to the end of the case.

The *sub-acute* variety of this septic synovitis of the hip will differ from the last simply in degree. Here the limb will also assume one of the positions described according to the stage of the disease, but softening of the structures in the joint does not take place to the same extent. The affection, however, is apt to recur at varying intervals, *e.g.* in gonorrhœa and rheumatism, and may run on into the chronic variety. The general treatment here will be the same as in the last form, but there need be no hurry about aspiration or incision, as the fluid may readily be absorbed, and leave behind no damage to the joint.

The *chronic* form differs so little except in its aetiology from the chronic strumous affection, that it need not be described separately here, the course of the disease and the treatment called for being practically the same.

Syphilitic disease of the hip is not commonly recognised, although not unknown in one or other of the forms described already. The epiphysary affection met with as a consequence of congenital syphilis has already been alluded to as far as necessary at present. The whole subject calls for much wider study before the exact position of this class of affections can be distinctly defined.

Strumous disease comes next as one of the commonest affections of the hip-joint. The general pathology of struma has already been briefly alluded to (p. 342), the local condition alone remaining to be considered. This may have its starting-point either in the head of the femur, the acetabulum, or the synovial membrane. And though exact data bearing upon this point are wanting, it is probable that this is about the order of relative frequency. When the head of the femur is alluded to here as the commonest starting-point, it should be understood that the growing epiphysary line is meant. The earliest evidences of a morbid process here appreciable to the naked eye are found in the form of patches of osteo-myelitis *granulosa*, usually caseating in parts, bounded on one aspect by the epiphysary cartilage, and on the other by the cancellous tissue of the bone, unless the process have started actually at the periphery of the epiphysal plane, when a third boundary will be formed by the periosteum for a variable distance. A good illustration of this is seen in a wax model in the Museum of University College, No. 796, showing the head of a young femur in section, where the disease is just commencing. The nature of these *granulating patches* have already been discussed (p. 342), the results of the process of which they are the earliest expression remain to be considered. Wherever it starts from, the process will eventually spread either to the encrusting cartilage or to the periosteum of the neck, unless it terminate in early recovery. In the first case the cartilage will be destroyed in the way already described (p. 350), and the disease become general

in the joint. In the second the cartilage may completely escape a direct attack, the disease spreading instead over the whole surface of the epiphysary plane, until a soft layer of granulation-tissue is interposed between the head of the bone and the neck. If this tissue now degenerate, the head is completely separated from the shaft, and is only fixed by the ligamentum teres.¹ This will account for those cases in which during excision the head is found perfectly loose in the joint unattached to the neck, and probably also detached from the ligamentum teres. Again, the process may commence excentrically, and spread only along one part of the border of the epiphysary plane under the periosteum and its synovial covering. Here it may provoke a plastic exudation, uniting the femoral and capsular layers of the latter for some little distance around. The softening process may then spread through this area into the extra-capsular structures, without involving the general joint-surfaces at all. Arrived outside the capsule, the granulation-tissue may soften and give rise to a fleshy abscess, which, on reaching the skin, may burst, leaving a track leading down to the diseased bone, but not into the synovial sac, the two layers of the latter being united around the sinus. The pus in such cases usually travels backwards and outwards, pointing not far from the trochanter, but internal to and below it. Such cases are puzzling to the surgeon. His probe passes down to diseased bone in the neck, and yet he can satisfy himself by the movements of the joint that neither the articular cartilage nor the general synovial membrane is involved. Such a condition of things must, however, be regarded as the exception. Usually the inflammatory process having reached the surface of the neck, spreads generally over the whole synovial tract of the joint, producing the typical strumous synovitis.

Now when the disease commences in the acetabulum it goes through phases precisely analogous. Beginning in the growing line of the epiphyses, it may spread in exactly the same form, either through the cartilage directly into the joint, or run along the synovial tissue in the cotyloid notch, to open eventually outside the capsule, leaving the interior intact; but this is rare. Finally, it may, with or without extensive damage to the joint, spread towards the pelvic aspect of the acetabulum, and eventually form an abscess there. The latter may then secondarily make its way either into the joint through the diseased epiphysis, macerating the bone and giving rise to the formation of sequestra (fig. 80), or under Poupart's ligament into the thigh, simulating psoas abscess, or into the ischio-rectal fossa.

If the diseased process start in the synovial tissue, we find its first traces in the abundant loose tissue of the cotyloid notch, which is seen to be gradually converted into soft granulation-tissue, as already described (p. 342). This pulpy change then extends to the rest of the synovial membrane. With it there is effusion into the joint, as a rule usually moderate in amount, and only mildly inflammatory. If the granulation tissue thus formed caseate, as it frequently does, and soften, the products will make their way just as often in a direction away from the joint through the capsule as inwards, affecting the bone. If an extra-capsular abscess be thus formed, it may actually save the latter. But if the caseation progress towards the joint, the latter is practically converted into a large caseating abscess, in which the bone is soon deeply implicated. For instance, the converse of what was mentioned above may occur—namely, the inflammation may now attack the growing epiphysary lines of femur or acetabulum, and thus sever the head from the neck; or the three bones of the acetabulum from one another, thus spreading into the pelvis. Finally, it may destroy both the surfaces of the joint alone by direct irritation.

The question now arises, Is it possible to diagnose between the affections arising in these three situations? If this question refers to the earlier stages, it may be answered in the affirmative; at all events as regards the femoral and synovial forms.

When disease is early and still limited to the head of the bone, the only evidence of its existence may be a slight and hardly painful limp, with perhaps a tendency to

¹ It is stated by Hyrtl that the vessels of the ligamentum teres do not communicate with those of the cancellous substance of the head of the bone, and consequently that the nutrition of the head does not depend upon them.

a little flexion of the limb when in repose. Examination so far will show neither heat, tenderness on moderate pressure, redness, nor fluctuation. The limb may be freely flexed and circumducted by the surgeon without producing pain, and no roughness of surface will be found. Plainly, then, there is no synovitis present, with its inflamed and tender surfaces rubbing one over the other; the capsule then is intact still. If, however, the trochanter of the affected side be pressed towards the acetabulum, or if the knee be struck in the direction of the axis of the femur, pain is at once felt in the joint. The fact is, that it is only when the diseased part of the bone is pressed upon that pain is produced. Thus throwing the weight of the body upon the head will strain the inflamed bone at the epiphysary line, and cause the

FIG. 73.

Y represents the acetabulum, Y, the ilio femoral ligament and strong and rigid part of the capsule, F the femur. The head is here resting against the acetabulum pressed into it by the weight of the limb acting on the Y as a fulcrum; the stroke across the neck represents the area of disease.

pain which finds its expression in the wince or limp of the child in walking. This wincing is also observed if the limb be gently over-extended, the head being thus thrust against the acetabulum by the leverage of the femur acting on the Y-ligament and the tense anterior part of the capsule as a fulcrum (see fig. 73). It is for this reason that the patient involuntarily flexes the thigh somewhat to relax the latter a little, and so relieve the pressure on the head due to the weight of the limb acting on the same lever (fig. 74).

Now, if synovitis were present, even supposing we were unable to detect either heat, redness, fluctuation, or tenderness on pressure, we should still find that the patient had involuntarily fixed the joint to avoid any movement of its inflamed surfaces one over the other, and if passive flexion or rotation were attempted, would resist voluntarily, with expressions of acute suffering. The thigh would be fixed in

FIG. 74.

Letters as in the last fig. D represents the diseased area. Here the limb is supposed to be flexed in order to decrease the pressure of the head against the acetabulum and so relieve the strain on D, of course the head is only theoretically withdrawn from the latter.

the characteristic position of synovitis (fig. 72). These points will serve to distinguish the two conditions from one another as long as they are distinct.

The diagnosis of the femoral from the acetabular affection is, however, most difficult in the earliest stages, if not impossible. Fortunately it is not as important to determine which of the bones is the starting-point of the disease as it is to make out whether the latter is commencing in the head of the femur or synovial tissues.

So much for the earliest manifestations of the strumous affection. When the changes already mentioned of caseation or softening of the granulation-tissue have affected the joint surfaces generally, the relations of parts soon become materially altered, and afford very plain evidence of what is going on. In the first place, all the evidence of subacute synovitis in the stage of effusion and softening will come on—

heat, tenderness, and swelling, with flexion, adduction and inversion, &c. ; the patient in standing will have the knee of the affected side carried across, above that of the sound ; the toe will rest on the ground, with the heel drawn up. If in bed, he will now lie on the sound hip (compare p. 363), with the other knee drawn up and resting across the healthy thigh on the bed ; the fold of the nates will be gone. The pelvis, whether the patient is standing or lying, is raised on the affected side (fig. 75, II.) This is simply due to the desire to bring the limb, strongly flexed and adducted as it is, into a direction more or less parallel with the sound one for convenience sake. If AB represent the spinal column, CD the transverse axis of the pelvis, CE the affected, and DF the sound limb, the angle BCE being a fixed one, any movement in the direction of the arrow in order to bring CE parallel with DF must have the effect of raising C , and with it that side of the pelvis (fig. 75, II.) At the same time D

FIG. 75.

(I) AB , the spine, CD the transverse axis of the pelvis, BCE , the fixed angle of the diseased side. (II) In bringing CE parallel with DF the angle BCE remains as before, but that side of the pelvis is raised and BDF is opened. In order to keep A perpendicularly over B the lumbar spine AB has had to curve.

will be depressed, and the angle BDF opened, there being no fixation of this joint. The consequence is an apparent shortening of the diseased limb as compared with its fellow, although CE actually remains of the same length as before. It is now parallel to DF , but is on a much higher level, so that only the point of the foot can reach the ground. And further, as a consequence of this raising of the pelvis on one side, a certain amount of lateral curvature of the lumbar spine is produced towards the opposite side. This will be easily understood by a glance at fig. 75, II. If the spine, A , were a rigid pillar, fixed firmly to the pelvis, represented by the line B , it would now slant away from the perpendicular. But being flexible, the patient involuntarily brings the upper part of it into the erect position, with the result of creating a curve below, AB .

Another result of the fixed position of the joint is seen on the spine when the patient stands up, or when, lying in bed, any attempt is made to correct the flexion of the thigh. This is the antero-posterior curve of the lumbar part of the column

produced by the rotation downwards on its transverse axis of the pelvis as it follows the limb (see figs. 76, 77). Here it will be seen that the angle PAF is the same in both conditions of the limb, representing the fixed joint, while POs has opened considerably, indicating the bend in the lumbar spine away from the perpendicular, so .

The next change in the affected limb is real shortening. To estimate the amount of this, which is important, it is best to place the sound limb in as nearly the same position as the other, and then measure from the anterior superior spinous process of the ilium to the lower border of the patella and to the inner malleolus. What the amount of shortening will be depends upon several points. If the limb have from the first been kept in the extended position, the head will simply crumble away slowly, and then the neck, until finally the trochanter comes to rest against the acetabulum, which has become simply flattened, or in some cases a little deepened by the destructive process. In such a case the shortening, measured as above, will be but slight,

FIG. 77.

Letters as before. Here the thigh has been brought down to the same plane as the other. PAF remains the same, consequently PO is altered in direction, and the lumbar curve is much increased.

probably under three-fourths of an inch in a child. If, on the other hand, the limb have been left to itself from the beginning of the softening process, and have consequently become strongly flexed and adducted as described, the carious head rubs against the upper and posterior border of the acetabulum. Then not only does the head, now half out of the acetabulum, crumble away, but also the corresponding part of the latter, until finally there is nothing to hold the thus flattened surfaces, and the head slips on to the dorsum ili, producing very considerable shortening even up to two inches or more. In this we have an example of the 'dislocation by destruction' of Volkmann (conf. p. 371). In such a case, unlike the dislocation by distension (p. 366), there would be no hope of achieving much by reduction of the dislocation, the form of the acetabulum having been altered, so that it could not retain the head

even if replaced. Before very long, too, the remains of the cavity are filled up with plastic matter, and the depression is obliterated (fig. 79).

From all this it will appear that strumous hip joint disease might be divided roughly into three stages, (1) that of simple inflammation without shortening, (2) that of shortening without dislocation, (3) that of dislocation. Another division, purely clinical, but nearly corresponding to the pathological just given, is also useful for the student. It indicates, also, some very important features in the disease mentioned above. This is (1) the stage of flexion with abduction and eversion, (2) that of flexion with adduction and inversion without shortening, (3) that of flexion, adduction and inversion with shortening. These clinical phenomena, it will be seen, correspond pretty closely with (1) inflammation without softening of the capsular structures, (2) softening of the latter, but little or no destruction of bone as yet, (3) softening of the capsular structures with loss of bone substance. With this division it would have been easier to speak more distinctly on the question of treatment suitable for the different phases of the affection.

FIG. 78.—Dislocation of Hip from disease. (From a preparation in the Museum of St. George's Hospital.)

FIG. 79.—The Acetabulum almost filled up with bony deposit after recovery from Hip-disease, in which the head of the femur was dislocated. (From a preparation in the Museum of St. George's Hospital. Series iii. No. 90.)

The *treatment* of these strumous affections of the joints, as far as it is general, has already been considered (p. 343), where we have seen that what is most called for is absolute functional rest for the part, with improvement of the general vitality of the body and local measures to reduce hyperæmia. In the case of the hip, the first of these calls is not difficult to meet, if the patient be confined to the horizontal position. But such confinement would in most cases be injurious, as tending to debilitate the patient and so to lower his vitality. It should not therefore be resorted to except in very early cases, and where a properly constructed couch on wheels would enable the patient to have fresh air and change. Fortunately, we possess means whereby the limb may be completely immobilised, and at the same time the patient be allowed both fresh air and even exercise of the other parts of the body. One of the best of these is the splint and patten, devised by Dr. Thomas. This consists of an iron band covered with leather fixed above to a girdle of similar structure which embraces the thorax, and running down behind the thigh to the lower part of the leg, following the curves of the loin, hip, and knee: it has a half collar above the latter, and at its lower end, to keep it directly in the middle line. The curve at the buttock should be very slight, so that it lies well into the depression between the great trochanter and the *tuber ischii*. Lying thus, it is fixed to the body not only by the girdle with its strap above, but also by a broad flannel bandage at the

waist and another around the limb. If there be any marked flexion of the limb, the back band is bent so as nearly to meet it but not quite. Bound to this the thigh is brought down little by little each day, the iron band being more and more straightened as this takes place, until complete extension is attained. To obviate the inconvenience of holding the limb thus, while walking with crutches, and to prevent all possibility of striking the foot upon the ground and so causing a jar to the diseased joint, an iron patten is screwed on to the sole of the boot on the sound side. Upon this and his crutches the patient now walks, if old enough, the affected limb being raised clear of the ground. In all the stages of disease, except that of dislocation, this splint is invaluable if carefully applied. But if not accurately fitted and adjusted, it is very prone to slip round to the outer aspect of the thigh, where it is of no use. It is also rather difficult to correct any ad- or abduction with it. Its great advantage lies in its giving complete rest to the limb, while allowing of regular exercise of the whole body; it also allows of free access to the joint for any local remedies which may be applied.

Plaster of Paris and starch bandages may also be used to immobilise the limb, but are not as a rule considered desirable appliances, preventing as they do completely all access to the joint, and being very difficult to keep clean. If it be considered desirable, however, to reduce the deformity of flexion, &c., under chloroform, plaster of Paris will retain the limb in a straight position, very completely and comfortably, if applied over cotton-wool.

Sayre's splint, by the use of which he proposed to transfer the weight of the body directly to the knee through a steel rod fastened above to a pelvic girdle and below by plaster to the thigh and knee, is not in use now-a-days in this country or on the Continent. Practically, it does not effect its purpose for long. Another appliance strongly recommended by this surgeon, for young patients, is a wire-woven cradle for the body, continued into two hollow back splints of the same structure for the lower limb; lying in this, well padded, the child is kept extended with the limbs at perfect rest, and can be carried about securely without damage to the joint. These 'wire breeches,' as he calls them, have the advantage of being able to correct ab- or adduction, and rotation, and of enabling the patient to evacuate the bowels and bladder without difficulty or lack of cleanliness.

In those cases where there is acute pain with much deformity and constitutional irritation when the patient is first seen, it is best to leave him in bed. He can be soonest placed in a condition of rest, the pain can be relieved by anodynes, leeching, or warm fomentations, and the deformity overcome either by immediate straightening under chloroform (a questionable practice), or more slowly and safely by extension, with a weight, as already described (p. 365). If there be much tension in the joint, the general symptoms will be much relieved by either aspiration or free incision, as already described (p. 335). The former, performed with every precaution against septic inoculation, will often suffice to tide over a critical point in the disease, and give the distended capsule rest. As soon then as the patient is easy, and the limb fairly straight, a Thomas's splint can be applied, and he can be allowed to leave his bed and to take exercise in the open air. But where incision has been practised, it will be necessary to confine the patient to bed. Here the weight extension will still be found the most suitable for keeping the limb in good position. If it should tend to in- or evert to any extreme degree, sand-bags at either side of the knee will usually suffice to counteract the tendency. In some few cases this is not so, and adduction of the limb may be a troublesome feature. Here a long splint bracketted opposite the wound, running from the axilla to below the sole of the foot, will best maintain the straight position and rest.

As to the next two factors in the treatment of strumous hip disease, *i.e.* improvement of the general vitality of the body and reduction of the local hyperæmia and effusion, little remains to be added to p. 343, except to notice that this joint is so thickly covered with soft parts that external remedies act less effectively on it than on others. At the same time there can be no doubt that repeated blistering over the front and back of the articulation is of real use in the earliest stages of the disease

and should be tried in all cases. Again, here if anywhere, the intra-synovial or even intra-osseal injection of solution of carbolic acid ought to be of use, and might be employed (see p. 343).

By one or more of these methods combined the inflammation in the joint may be brought to a standstill in one or other of its stages. Thus hyperæmia may be checked at the outset, and a complete *restitutio ad integrum* result. Or if a little plastic material have been effused into or about the articulation, the process may go no farther, nothing but some slight adhesions being the result. In such a case, as soon as we have reason to believe that all hyperæmia has disappeared, passive motion, with or without an anæsthetic, will restore the normal functions of the joint without further trouble. In beginning passive motion a little difficulty is sometimes experienced in fixing the pelvis which moves with the femur in all directions as it is moved about. This may be best obviated by placing the patient upon a hard surface, and then directing an assistant to hold the sound thigh firmly down in the position of complete extension. This will fix the pelvis, and prevent it from following the affected thigh, when it is now flexed on the patient's abdomen. Circumduction may now be effected without much difficulty. Other means of fixing the pelvis will usually be found inadequate in such cases; fortunately this method meets all our requirements.

Where anything more than slight adhesions exist in the hip-joint the greatest caution should be exercised in attempting to restore its functions by passive motion. The enormous leverage we possess through the length of the femur should be remembered in the first place, and then the ease with which the neck of the femur could be broken through at the epiphysary line in a young subject, especially if it had been recently inflamed, supposing the head were fixed to the acetabulum. It should be remembered, too, that to start the disease afresh in a very bad form is a heavy price to pay for an attempt to restore an amount of movement to the joint, which would not, in some cases, be missed, owing to the free compensatory movements of the pelvis which soon become developed in these cases.

After passive movement has been pushed to the extent of tearing through adhesions, it is well to fix the joint and to apply local antiphlogistics for a few days. There is not unfrequently a little reaction calling for these measures, which, however, are usually sufficient in well-chosen cases to allay all dangerous hyperæmia. In those unfortunate cases where want of judgment has led to forcible movements of joints, from which active disease has not yet disappeared (such cases are seen in the practice of the so-called 'bone setters'), or where union was too complete to admit of any safe restoration of mobility, and where, consequently, active disease has again been lighted up, the same rules of treatment apply as though the disease were primary.

We turn now to those cases where either our treatment has been ineffectual in checking the march of the primary disease towards destruction of the joint surfaces with loss of bone, or where the patient has been brought to us in that state, or, finally, where destructive disease has been rekindled. Here one of two ends must be kept in view, (1) either by providing a free escape for all the products of the destructive process as they are shed off to bring about a healthy reaction in the joint, or (2) by at once removing the diseased structures, in and about the latter, by excision, to leave it in a condition to heal at once. The ultimate result aimed at in both cases is the same—namely, the union of the two bones of the joint by sound tissue, fibrous or bony, *i.e.* fibrous or osseous ankylosis (see p. 359). For the consideration as to which is the best direction in which to work, the reader is referred to the essay on **Excision**. Here it is only necessary to say a few words as to these two modes of repair after strumous disease and their consequences as regards this joint.

When the morbid process has resulted in destruction of the articular surfaces of the bones of the latter, the carious head of the femur lies in contact with the acetabulum, probably in a similar condition. Now, if they be kept thus in a state of rest, the fluid thoroughly drained off and the patient restored to good general health, the two bones may unite just as a compound fracture does; that is, granulations spring from both inflamed and softened surfaces, coalesce and organise either into fibrous tissue or bone

(p. 359). If, on the other hand, the health remain bad, or the part be not kept at rest, or the pus be only imperfectly drained off and allowed to become foul, the inflammatory process extends deeper and deeper into the bone, more rapidly even than the actual disintegrating change, and the morbid condition is indefinitely prolonged. In this way the whole head, neck, and acetabulum may be destroyed. Should the patient survive this very exhausting process, which so often brings with it the well-known amyloid changes in the internal viscera, repair may however still result through fibrous or bony tissue. In what state of usefulness the limb is now left depends upon the treatment adopted throughout as to deformity. If it have been kept straight or nearly so by weight or splint, the patient will have an excellent limb to walk upon, and especially if the union be fibrous, as is sometimes the case; for then flexion and extension may be possible to small extent, rotation and abduction rarely. And though there be considerable shortening, it is made up for by a droop of the pelvis on that side. With osseous union a perfectly straight bone is not so desirable, the patient being unable to sit down comfortably with it, and the gait being very stiff. Union with slight flexion is better in this case, the foot being thus brought into better position for compensating for the loss of length by pointing of the toe, and the gait is more easy and the step elastic. The patient can also sit down better.

But in cases left quite to themselves, or neglected as regards position while anchylosis is taking place, the results are most deplorable, whether the union be fibrous or bony, but especially with the latter. Here the marked flexion of the thigh, combined with its shortening, prevents the foot from being placed upon the ground, besides which the extreme adduction brings the limb across its fellow to a great extent, perhaps even more than can be compensated for by tilting of the pelvis. Again, the genitals are sometimes interfered with, causing in the female trouble in micturition, and preventing procreation. Not infrequently, owing to one or more of these discomforts, an operation is called for if the anchylosis be osseous. If fibrous, prolonged simple extension will often effect much, even in extreme cases, or this may be aided by subcutaneous section of the fibrous bands with a tenotome. If these means fail, or if the union be osseous, nothing is left but to divide the bone below the point at which it is fixed.

This operation has been especially brought into notice in this country by Mr. W. Adams, and has been frequently practised. The occasions for its use, however, it is to be hoped, will become more and more limited with each year as the necessity of keeping the limb in a favourable position during the process of consolidation is more fully recognised, and the methods of accomplishing it more generally understood. The procedure is a simple one, all things considered, and safe in these days of antiseptic surgery. It consists in making a short incision down to the bone at the point to be divided, and in cutting through the latter either with a narrow lock-saw, as preferred by Mr. Adams, or a chisel, now perhaps more generally used. The point of the bone selected for division varies in different cases. Where but slight destruction has taken place and repair has quickly followed, the neck may be, and is usually chosen. But where head and neck have both been destroyed, a spot about two inches below the top of the trochanter major is selected. In the first case the incision is made behind and above the neck, in the last on the outer aspect of the femur. The choice between the saw and chisel will probably remain a matter of individual opinion for a long time to come. In a considerable number of osteotomies of the femur, the author has always found the tool known in London as *Maunder's chisel* most satisfactory, and gives it the decided preference over the saw. When inserted as far as the femur, a number of smart raps are given to it with a light mallet, which drives it into the bone. It must be loosened at intervals by a rocking motion, and though withdrawn from the bone if necessary, it need not be withdrawn from the soft parts, which should be kept closed around it by pressure of a soft carbolised sponge. The saw requires a more extensive division of the soft parts, and besides lacerating the latter somewhat, leaves a good deal of bony debris behind in the soft tissues. On one point, however, all surgeons are agreed—namely, the need of the most absolute

cleanliness during and after the operation, and the use of either the Listerian or other antiseptics.

A few words now remain to be said regarding the effects of that form of hip disease in which the acetabulum is extensively involved. The process by which this structure is destroyed has been already described (p. 371). It has been there shown that an abscess is not infrequently produced by it on the pelvic aspect of the acetabulum. This will now either discharge through the latter into the joint, or will run forwards over the ramus of the pubes to point on the front of the thigh, where it may be mistaken for psoas abscess, or it may run downwards to the sciatic notch, and then outwards to the back of the buttock. But before the pus has been evacuated in either of these situations, it has usually done considerable damage to one or other part of the *os innominatum*. Thus by maceration of the bone and periosteum it may give rise to necrosis, varying from small fragments at the base of the acetabular cavity (Fig. 80) to almost the whole pubic bone or ischium, which may lie loose in great part in the abscess. Cases are on record in which these bones have been removed in opera-

FIG. 80.—Necrosis of the Acetabulum.
(From a preparation in the Museum of St. George's Hospital.)

a, head of femur, extensively exposed by abscess in the joint; *b*, tissue containing the remains of the ligamentum teres; *c*, loose necrosed portion of the acetabulum; *d*, perforation of the acetabulum corresponding to the necrosed portion.

FIG. 81.—Head and Upper Part of the Shaft of the Femur affected with chronic Osteo-arthritis. (From a preparation in the Museum of St. George's Hospital.)

tions for excision of the hip (Erichsen, 'Science and Art of Surgery'). It may, however, be fairly hoped that such cases with this very severe degree of necrosis will become rarer and rarer, until they are never met; the benefits of free drainage and early excision being now each day more fully recognised. No special directions can be given for dealing with sequestra about the acetabulum when present; they must be treated upon the principles which guide us elsewhere, the great aim being to remove them as early as possible, and to provide free drainage for the cavity left behind.

Gout, in the ordinary sense of the term, is not one of the common affections of the hip-joint. If met with here, it presents no special features, and requires no special treatment which need be described here.

What is known, however, as rheumatic gout, or *arthritis deformans*, has one of its favourite seats in the hip-joint. The nature of this disease has already been discussed (p. 344 *et seq.*) and it only remains for us to consider how it affects this particular articulation.

We find here, in the earlier stages, the same pearly thickening as elsewhere of the borders of the articular cartilages, both of the femur and acetabulum. In some cases at this time we find, too, distinct evidences of irritation in the form of congestion of the synovial fringes. This may even be sufficient to cause marked hyperplasia in the latter, amounting, I have seen, to the production of pendulous fibrous

bodies attached to their borders.¹ It may even go farther, leading to effusion in greater or less amount. But the inflammation in these cases is not acute, and is accompanied by but few subjective symptoms. But it is the secondary changes of this low inflammatory process as they affect this joint that offer matter for consideration. As a rule, we have here a plastic osteitis of so low a type that, while, on the one hand, it may soften the bone of the joint surfaces sufficiently to admit of their being moulded and altered in shape by the forces acting upon them, it may on the other hand produce new bone very slowly at those points of most irritation—namely, where pressure and friction are greatest. The consequence of this is that deformity is produced by the forces acting on the softened bone, while only a very imperfect attempt at repair is made. Thus we find in many cases the posterior and upper part of the acetabulum softened to such a degree that it has been unable to support the pressure of the head of the femur, and the latter has gradually moulded and pushed the material of the brim upwards, until it has come actually to lie above and behind the acetabulum in a kind of rudimentary socket, giving an example of ‘dislocation by deformation’ of Volkmann (conf., dislocations by ‘distension,’ p. 366, and ‘destruction,’ p. 371). This socket, however, is very imperfectly formed by a mass of spongy bone at first, which may eventually become sclerosed, and, in that case, even eburnated, until tolerably free movement is possible. The head during this time is also altered in shape variously, having usually large masses of new bone thrown out around its border beyond the limit at which it comes in contact with the acetabulum (fig. 81); this is at first spongy, but may eventually become hard and likewise eburnated. Again, the softening process may lead to the complete wearing away of the head of the femur, until the root of its neck alone plays against the other bone.

In other cases, however, the course of things is different; the head may press deeper and deeper into the soft acetabulum, while around the borders of the latter new bone is thrown out, deepening the cavity very materially. In this way the head may eventually be almost surrounded by bone, and its movements greatly restricted, or even in extreme cases completely prevented. This locking of the bones together by ‘deformation’ is rarely or ever accompanied by true synostosis, or fusion of the two surfaces together, such as takes place in ankylosis after destructive disease.

Sometimes these changes are accompanied by very marked and increasing adduction of the thighs, as though either the necessity for relief of the tense anterior capsular structures now irritated existed in these cases also, as already described for the counter affection (p. 369), or the enlargement of the head was actually thrusting it away from the acetabulum, and so levering the femur into the adducted position against the fulcrum of the Y-ligament, now too short for such an altered condition. This adduction sometimes brings the knees firmly together, and the patient is prevented from walking except from the knee joint; in other cases the limbs cross one in front of the other, and produce a very peculiar condition of progression, the knee alone being moved. This has been specially described under the provisional name of ‘cross-legged progression’ by Mr. Lucas,² who suggested various explanations of the condition. His paper, based upon two cases, not both arthritis deformans, was followed by the record of another case by Mr. Tyson,³ in which this disease was most probably the origin of the deformity.

As to the treatment of *arthritis deformans* in the hip, little need be added to what has been said already (p. 347). Once the disease has begun here, it tends in the majority of cases to grow steadily worse, taking one or other of the directions alluded to. The only local treatment likely to be of any avail is the use of systematic friction with liniments of a stimulating kind. In so far as these promote an active circulation in the part and increased vitality, they are of use, but only so far. Flannel coverings act in the same way, and should always be worn over the joint. In those rare cases where breaking down of the soft and hard tissues of the joint occur, and slow suppuration is the result, the question arises, What should be done? should the parts be

¹ *Trans. Path. Soc.* vol. xxx. p. 353.

² *Trans. Clin. Soc.* 1881, p. 20.

³ *Ibid.* p. 186.

excised, or simple incision trusted to? At present the answer would be decidedly in favour of the latter proceeding. If, as appears probable, the morbid process is the result of the lowering of vitality in the tissues with degeneration, the prospect of repair after so severe an operation would be very remote. And, indeed, even incision should be delayed as long as possible in the hope that the fluid matter in the joint may be re-absorbed. Most surgeons must be familiar with cases where a doughy swelling has formed at one spot over such a joint, with dusky redness and softness, where they have been satisfied that a breaking-down process and formation of fluid was taking place in this disease, and where, nevertheless, with rest, local and general treatment, the symptoms have disappeared and recovery with ankylosis has taken place. If, however, such a collection is about to burst, we have nothing left but a free incision, with scraping out of any morbid matter within reach; the whole operation to be conducted on the same principles which guide us elsewhere.

Loose bodies are not unknown in the hip-joint, though very rare, as already stated (p. 355), and their mode of formation has been indicated.¹ Owing to the structure of the joint, they appear, so far as is known, not to give rise to symptoms, or to call for treatment. I have not been able to find any case in which an operation was undertaken for the condition.

Mimic disease is not infrequent in the hip, and may give rise to errors of treatment, unless the surgeon is on his guard. A careful study of the characteristic positions of the limb in the various stages of the true disease will be our best guide here. The intense pain complained of will probably be entirely out of keeping with the absence of change of position as described, which ought to be very great if the disease were commensurate with the suffering complained of. Again, the fact that the pain will be generally referred to the hip itself, instead of the knee, in mimic disease will help us in reference to this particular joint. The general conditions, however, already noticed at p. 360 are the most important of all for coming to a correct diagnosis in any given case.

AFFECTIONS OF THE KNEE.

The knee, as second in importance to the hip, must next be examined.

Perhaps of all the joints of the body this is the most frequent seat of *simple acute synovitis*. Its exposed position both to injury and vicissitudes of weather, together with its functional activity, will account for this.

The subjective symptoms here are those enumerated as present in all attacks of this form of disease in any other part (p. 334), and nothing special need be added. The objective symptoms, too, require little particular notice. Here, however, the swelling will be particularly well marked and also the fluctuation, the part being so superficial. These are most notable at either side of the patella below and above it, for the reason that at these spots the coverings of the joint are thin. The patella in the straight position of the limb will be lifted off the articular surface of the femur and float, so to speak, on the synovium, but can be pressed down upon the femur with a little force. The knee, if left to itself, will now assume a more or less flexed position. The explanation of this is simple, and in harmony with what has been seen to hold good in the case of the hip. The fact is, that in the extended position of the limb, the parts of the capsule most on the stretch are the posterior structures, with the external crucial ligament. As soon then as inflammatory irritation commences within the joint, the patient instinctively relaxes these by flexion for their relief, the thin looser structures in front needing no relaxation. Attempts now to straighten the knee will be resisted, lest the tension behind should be increased. Further flexion, too, is opposed, so that the inflamed surfaces may not be swept one over the other.

Such, then, would be a case of simple acute synovitis coming on, for instance, after some injury, such as a blow or strain. It is not likely to be confounded with any other condition, unless possibly an effusion of blood into the joint, as is not

¹ Barker, *Trans. Path. Soc.* 1878, p. 353.

infrequently met with after violence, but a little care will prevent any mistake. In hæmarthrus the swelling sets in usually a little earlier than we would expect acute inflammation. Thus, within an hour or two of the receipt of the injury, the patient will find his knee distended with fluid and stiff. Then, he will complain of little or no real pain, though he may say perhaps that the part feels slightly 'sore.' There is no tenderness or heat about the latter, and though the skin may appear a little reddened possibly, it is not from increased vascularity, but from that inhibition of the colouring matter of the blood, which takes place so soon in most cases where blood is effused subcutaneously. If seen somewhat later, this colour may be a little mottled, with a suspicion of purple, or even green, as after ecchymoses. Again, the limb is not flexed in this case, and movement is not painful, although limited by the distension of the capsule. Finally, puncture of the latter with a fine, thoroughly cleansed needle will give exit to the blood and settle the diagnosis.

The general treatment of synovitis of the knee will be conducted upon the lines laid down already (p. 335). In addition here, the joint must be placed in the position of greatest rest, and so immobilised. This is best done by leaving the knee slightly flexed, and fixing it thus upon a Macintyre's splint. This apparatus is well suited to such cases, securing perfect rest for knee and foot, while giving free access to the part for the application of local antiphlogistics. But, if it is not to hand, a straight back splint, with a thick pad for support in the popliteal space, will answer very well. or a scored Gooch's splint. This fixation, combined with the local treatment indicated on p. 335, will usually suffice to check the inflammation and restore the functions of the joint rapidly. But, if the attack have been severe, and have lasted longer than is the rule, troublesome complications are not infrequently left behind. In the first place, there may be much stiffness of the joint, due to plastic matter effused in and about the capsular structures, and more or less organised, perhaps a little also between the ends of the bones uniting them, but not firmly (see Anchylosis, p. 358). When this state of things exists, after all trace of inflammation has disappeared, it may be remedied in some cases by easy passive motion without an anæsthetic, or, if this fails, as it sometimes will, by forcible flexion and extension with the latter. In this way the adhesions are either gradually or immediately stretched and torn, with a distinct crackly or rending sound, and sometimes, where much adhesion has existed, with a little effusion of blood into the joint. After this measure, it is generally desirable to fix the joint again for a day or two, and to reapply the local antiphlogistics, lest inflammation be excited once more. This is not to be feared if the patient be healthy; but otherwise there is considerable risk, if we have resorted to the forcible flexion too early.

Another change to be feared after these attacks of acute synovitis is that they may, either from neglect, want of energetic treatment, or constitutional fault, run on into the *subacute* or *chronic* forms of the disease. These hardly need any long description here, offering few special features in the knee not already considered (p. 336). It must be mentioned, however, that after the subacute affection, that condition already spoken of as *hydrops articuli* (p. 336) is oftener left behind in this than in any other joint. Thus the whole knee may, in extreme cases, look like a bag of fluid, the capsular structures not being even very tense, although many ounces of fluid may be contained in it. But the only trouble complained of by the patient is a sense of weakness in the part. Subjective symptoms are absent; the objective are only an exaggeration of those already seen in the acute form, but without the flexion probably.

As to the treatment of this condition, it is not difficult in most cases. Rest in bed, with repeated blistering or painting with Tr. iodi, and a few brisk saline purges, will often suffice to remove the fluid. But the latter in many cases returns more or less when the patient begins to walk again, unless precautions are taken; these should consist in very careful strapping of the whole knee with adhesive plaster, commencing about a hand's breadth below the patella and carried upwards (each strip well overlapping the one next below it) to the same distance above it. This covering of plaster should be covered by a bandage, evenly and firmly applied from the foot upwards.

A thin well-fitting covering of plaster of Paris, or starch bandage, is also of much use in these cases. These coverings should be worn for a considerable time, and should be replaced as they wear by similar ones, or an elastic web knee-cap, as long as there is the slightest tendency to refilling of the joint. When all tendency to this has ceased, and the fluid has nearly or quite disappeared, it is well to employ cold douches with sham-pooling, with stimulating liniments, for some time, to encourage a healthy vascularity in the part. If all these means fail to remove the fluid, it should be aspirated one or more times with all precautions as to antisepsis, the limb being strapped as above after each operation. If even now it refill, it is well, after emptying it by aspiration, to inject into the joint a small amount of some slightly stimulant, but perfectly antiseptic, fluid, such as carbolic solution of the strength of $2\frac{1}{2}$ per cent., or of iodine and water in the proportion of 3j to 3ij to the 3j. This, if carefully managed, excites a decided reaction in the joint, with some swelling and heat, which after a few days subside, and usually leave the part free of the tendency to fill up as before.

It is very desirable to treat these cases of hydrarthrosis early, before great distension has taken place. When neglected, the joint is very much weakened and is slow to recover even with the most suitable treatment.

In the *chronic simple form* of synovitis, this fluid effusion may also be associated with a good deal of thickening of the capsular structures, which may be converted by hyperplasia into soft pulpy tissue. But this produces a condition as to symptoms and treatment so similar to strumous synovitis, now to be considered, from which it probably only differs in aetiology, that one description will suffice practically for both.

The three forms of *septic synovitis*—the acute, sub-acute, and chronic—which we have already considered elsewhere (334), present no peculiar features as developed in the knee, and need not therefore be separately described. It is enough here to say that the acute form requires the earliest and most energetic treatment, if we are to save the joint at all. Aspiration is here rarely sufficient, and it is better, as soon as we can prove the existence of suppuration, to lay the joint open on both sides by free incision, and wash it out with carbolic lotion, then putting it up under an antiseptic dressing, with careful drainage and immobilisation. The incisions here, as above, should lie well back, so as to thoroughly drain the deepest part of the cavity. As to the sub-acute and chronic forms of the disease, if distension be great, aspiration repeated over and over again may be sufficient; but here, too, incision should not be too long deferred. In many cases, however, local antiphlogistics (p. 335) will be adequate for the local condition. The general treatment of the constitutional state has been already considered (p. 335).

Strumous disease of the synovial membrane of the knee differs in no respect as to aetiology and pathology from that met with in the same structures elsewhere (see p. 342). We have only then to consider here the subjective and objective symptoms due to the disease in this particular situation.

Very often in the early stages of the disease, the subjective phenomena are almost nil. There is little or no pain, heat, or throbbing. And yet objectively we have suspicious features about the case. Thus a slight fulness may be noticed above and below the patella on either side. This is due, not to the presence of fluid in the joint, but to thickening of the actual synovial tissues, in which those low plastic changes are taking place already described. There is consequently no fluctuation here, but a doughy or elastic sensation to the finger under palpation. Again the limb will usually be slightly flexed, for reasons already given in speaking of acute synovitis (p. 335), though to a minor degree. The whole joint, too, will look more bulky generally, but at first there will be no alteration either in the colour or lustre of the skin. Passive movement or walking will produce little discomfort, though some sensation of stiffness may be complained of.

Later on, however, when the ligamentous structures are being invaded by the inflammation, and are becoming softened and weakened, the symptoms will be very plain. Besides the exaggeration of the fulness already noticed, there will be greater flexion with pain on movement of the joint surfaces one over the other, although

perhaps little or none on simply resting the weight of the body on the bones without movement. The local heat will also be increased, and there will probably be a slight general rise of the temperature of the body. Tenderness will also be marked, usually most so at one or other side of the patella. In those cases where caseation or actual purulent softening is taking place, at one spot or other of the synovial or capsular structures, the colour of the skin will be deepened more or less by congestion, and the heat will be raised. But, even short of this, the skin over the swollen joint will be altered in appearance. It may be paler than usual, with a peculiar glazed lustre, and may be marked by many veins, which stand out in relief as blue lines against the general white tone of colour. As the condition advances to an extreme degree, all the symptoms become aggravated, and in addition we have another notable change, if the limb be left to itself—namely, actual displacement of the bones from their normal relations to one another. Thus we find besides the flexion, now extreme, that the tibia is actually drawn backwards on the lower end of the femur, which now projects in front with the patella; at the same time the tibia and fibula together are rotated more or less outwards, and as the patella follows, it now rests more or less upon the outer condyle of the femur. Fig. 82 represents this displacement in an extreme degree; its cause is not far to seek. It will be remembered that in this stage the ligamentous and capsular structures have become softened by the spreading to them of the low inflammation which commenced in the synovial membrane. In the flexed position of the limb, then, there is nothing to antagonise the strong action of the flexors in the ham, which in this position tend to draw the head of the tibia directly backwards, and as the ligamentous structures are soft, they gradually yield to the strain. Again, as the external hamstring muscles act at a greater distance from the axis of the tibia than the internal, they possess more power of rotation of the bone than the latter, and as the ligaments yield, the head of the fibula is drawn backwards faster than the inner border of the tibia, the result being rotation outwards of the leg and carrying outwards of the patella.

As to strumous disease in its relations to the ligamentous and cartilaginous components of the joint, it may be stated never to arise in these primarily. As to the first, we have already seen that they are eventually involved in the slowly advancing change of the synovial structures, and are fused with them into a soft spongy granulation material. As to the second, it is sooner or later affected in a secondary way by those changes already described (p. 349). Thus the hypertrophied synovial fringes swelling in all directions will travel across the surfaces of the joint, until between the two bones there lies a layer of granulation-tissue. Whenever this touches cartilage, it will produce eventually proliferation of its cells and ulceration. This may go on to partial or complete destruction of the articular covering. But this disease never commences primarily in the cartilage.

Turning now to strumous disease of the knee commencing in the bone ends, it may be stated at once that the starting-point here is usually an epiphysitis (see p. 353) either of the femur or tibia. This, resulting in an osteomyelitis granulosa, gradually sends up through the end of the bone into the joint processes of inflamed medulla, which bore through the encrusting cartilage as already described. In the joint they produce the same gradual destruction of the cartilage as the spongy inflamed synovial

FIG. 82 shows the characteristic position assumed by the Knee-joint when left to itself in advanced Strumous Disease of the Synovial Membrane, viz. flexion, rotation of the tibia outwards, its partial dislocation backwards, dislocation of the patella outwards. (From a preparation in the Museum of University College.)

membrane has been seen to do. And, not only this, but the inflammatory action may spread to the latter, and produce in it the same changes as those resulting from primary disease of its own structures, already considered. In such a case as this we have all the structures of the joint diseased, and shall probably be unable to distinguish in any particular instance which is most so. On the other hand, we not unfrequently meet with instances of strumous disease in the bones of the knee-joint in young children, which does not affect the articulation at all primarily, and may be prevented from doing so secondarily if diagnosed early and judiciously treated. This strumous epiphysitis, namely, has tended to spread rather along the plane of growing tissue at the end of the diaphysis, and to present at the periphery, under the periosteum, outside the synovial cavity of the articulation proper; unlike the hip and shoulder, where the epiphysary lines lie inside the capsule.

It may be well now to consider for a moment some points of diagnosis between the different forms of the affection when seen early.

If the synovial membrane be alone the seat of the change, the knee will be but very little swollen, and some of the swelling will be due to slight effusion into the joint, which may be now felt to fluctuate. But there will be a little pulpiness about the thinner parts of the capsule not present in ordinary synovitis, and yet not sufficient to indicate that the change has reached the capsular structures. The latter, too, not being inflamed, there will be little pain on movement, and not much instinctive desire to flex the part. The outlines of the bones are unaffected, and resting the weight of the body on them is not accompanied by pain.

If, on the other hand, the capsular and ligamentous structures be involved in the pulpy change, the swelling and roundness of the knee will be well marked with a doughiness of the most prominent parts, which will mask any little fluctuation which may be present. The subjective symptoms will be more marked also; but besides this, flexions will be present, as also pain on any movement which stretches the ligaments. As yet there is none of that starting of the limb already described as frequently present when the cartilage is becoming eroded. Nor are the outlines of the bones in the least masked at present.

When, on the other hand, the disease starts in the ends of the bones, pain and limping are some of the earliest symptoms. These may be present before any flexion is noticeable. The weight of the body is early felt on the tender ends, and the position of flexion will be assumed at last, in order that the surfaces may not be kept firmly pressed against each other by the action of the ligaments in the extended position. But when the patient is lying down, the part may be freely moved backwards and forwards if it be not too firmly extended, the rubbing of the still healthy joint surfaces producing no discomfort. Then there will probably be a good deal of gnawing pain in the ends of the bones, especially at night. The latter, too, will be more or less expanded, and may be felt altered in outline to a slight extent; they will also be tender just above and below the joint surfaces when pressed upon from the sides. In those cases, too, where the disease in the bones is spreading along epiphysal planes, we shall find in addition to these symptoms other more distinct evidence developing later on. Thus we may find one spot on the external or internal surfaces of the condyloid portion of the femur becoming tender and swollen over a limited area: later this may acquire a dull red colour, and give a doughy or fluctuating sensation to the finger on palpation; then this collection may burst externally through the skin and externally also to the synovial cavity of the articulation, and our probe may be passed to a greater or less depth into the bone, but not into the latter, unless in advanced cases. The same evidence may also be forthcoming that the head of the tibia is diseased alone and independently of the joint surfaces, the external abscess pointing through the skin in this case about half an inch or an inch below the articular surface of the bone.

But when the disease in any of these situations becomes advanced, it is almost impossible to diagnose in which it has originated, or indeed in which of them it is most advanced in many cases.

Turning now to the treatment of strumous disease of the knee, the synovial and bone

varieties may be taken together, what is suitable for one being equally so for the other up to a certain point. The general constitutional treatment of struma has already been alluded to, as far as necessary (p. 343), as also the local antiphlogistic management. It is only necessary, then, here to point out how the latter can best be applied to the local condition of this particular joint.

In the first place, rest has to be secured for the knee without interfering with due exercise of the rest of the body. In very early cases, and with intelligent children, it will be enough to immobilise the joint with a padded back splint of leather or wood, and allow them to go about on crutches in the open air, the knee being treated locally with blistering, painting with tincture of iodine, or scoring with the actual cautery. But with many young people the desire to use the limb will be too strong for them, whether they are on crutches or not. Under these circumstances nothing can be better than Dr. Thomas's splint, which will prevent this and at the same time enable the patient to have a fair amount of exercise, eventually without crutches. This appliance consists of a strong circlet of iron covered with leather, which embraces the thigh on the affected side, so that a padded portion of its circumference may rest against the under surface of the *tuber ischii*. From this collar two strong iron rods run down at either side of the limb to about two or three inches below the sole of the foot, where they both terminate in a ring of iron, flat towards the sole. To this ring the foot should be fastened with strips of plaster, making extension in the usual way. The vertical rods, running now at either side of the knee, are fixed to the latter either by turns of bandage or, better still, by a broad leather sheath stitched to the rod at either side, so as to support the back of the knee, combined with circular bandaging. With this splint applied the patient rests, when in the upright position, with his *tuber ischii* seated upon the iron circlet above, and the whole weight of the body, on this side, thrown upon it, and through it to the side rods and foot-piece, the foot itself being prevented from reaching the ground. With an iron patten screwed on to the sole of his boot on the sound side, he is now able to walk about (at first with crutches) very fairly, the knee being at perfect rest and undergoing any local treatment all the time. After a while, when the power of balance is acquired, the crutches are put aside and the patient can walk well, though of course stiffly.

This splint is suitable for every stage of the disease, wherever it commences. It is one which can be easily made and readily applied or removed. With it any tendency to flexion of the knee can be combated in the earlier stages by extension to the foot-piece. Even later, where flexion has been neglected and has become extreme, the limb may be brought down straight by a combination of extension with pressure and counter-pressure on the knee forwards and backwards, by means of leather sheets passing across above the joint, in front of the lower end of the femur, and below, behind the calf. The extension may be made a continuous and elastic one by the insertion of an elastic ring between the foot-piece and the extending straps of plaster. Broad straps of india-rubber may also be used above and below the knee, instead of leather, for the same purpose. Other appliances may of course be used for immobilising the knee, such as plaster of Paris or starch bandages; but there is an objection to these, that they prevent the employment of local remedies, and they do not take the weight off the limb. But with Thomas's splint we can treat a case from beginning to end in any stage, from the milder to the worst forms of suppurating joint.

If the actual cautery is considered a desirable counter-irritant in any case, and I know no better, it may be used either in the form of light strokes with a narrow iron on the lateral aspect of the joint, so as to produce rapid blistering, or it may be applied over one large surface, about 1 x 3 inches, more vigorously with a flat instrument, so as to make an open suppurating surface, as practised by Syne. This may be kept open with Ung. Sabin. all the time the patient is taking exercise on his splint.

But, in spite of all our care, or in the absence of any treatment, such cases of strumous disease of the knee will often run on to the formation of caseous material,

either in the massive granulation-tissue, derived from the synovial and capsular structures, or in the head of the bone. In the former case, however, it does not at all follow that the softening action may open up the joint surfaces. In a very large proportion of cases, caseation having commenced in the peri-synovial tissues, forms an abscess, which may extend widely, and eventually open through the skin without implicating the joint proper at all. The extent to which this is possible is very remarkable, and cannot be too often insisted on, as errors are very apt to arise from overlooking the fact, and a joint or limb may be sacrificed in the belief that the sinuses, leading deeply downwards, actually run into the articulation. I have seen amputation through the thigh performed on the supposition that several sinuses around the knee led into the joint, and that the latter was consequently disorganised, and where subsequent dissection showed that the encrusting cartilages were healthy, and the joint unopened by the suppuration, though the soft parts were freely traversed by sinuses, external to the synovial lining. In this case the knee and limb would apparently have been saved by an opening up of the sinuses and scraping out of the caseous materials from the peri-articular abscesses. Such treatment will often afford just as good results in very young persons, even if the joint should be opened during the operation, as a free excision would. If it be adopted early when the breaking-down process is commencing, a simple incision being made antiseptically into the boggy focus, and all the diseased tissue scraped away with a Volkmann's sharp spoon, the spread of the disease may be prevented, and the resulting cavity will heal rapidly.

The same almost may be said of that form of the disease commencing in the ends of the bones, particularly the tibia. This may advance to a considerable stage of development without actually invading the joint. A knowledge of this, and of the fact that the disease frequently commences in strumous epiphysitis, may lead us in the future to examine this part of the bones much earlier for evidences of morbid action, and when we have found this to operate early upon the condition before it spreads far. Our line of action in such cases is to cut down upon the tender spot over the epiphysary line (with all care to protect our wound from impurities) and then to scrape away with a sharp spoon any diseased tissue that may be found there. The resulting cavity should be kept open with a drain-tube, and allowed to granulate up from the bottom. It should never be forgotten, however, in operating upon this part of a bone, that we are dealing with a very fragile tissue, and that any undue force or roughness in scraping must be carefully avoided, lest we damage the growing tissue around which we are leaving behind. With due care many joints may be saved by this simple operation, but without the gentlest treatment it may do more harm than good.

In those cases where the disease, starting either in the synovial tissues or the ends of the bones, actually spreads to the surfaces of the joints, and causes destructive and increasing change there, either accompanied by suppuration or without it, the question will arise as to whether the joint can be saved by anything short of excision. Leaving the discussion of this point in detail for the essay on EXCISION OF JOINTS, it may be stated here shortly that the knee in this state can be often saved by free incision with careful drainage. The best incisions to make for effecting the latter purpose are those to the benefits of which attention has been drawn by Mr. Rushton Parker, of Liverpool. These are made at either side of the joint over the condyles, but well behind, so as to drain the back part of the cavity. They should be very free and open up the synovial pouch freely. When made, the limb should be immobilised on a Thomas's or Macintyre's splint, and the joint washed out occasionally with carbolic or tincture of iodine solution, all dressing and treatment being conducted on the best antiseptic principles. This thorough drainage, if it be maintained, is frequently followed by the best results, the cavity gradually filling up with plastic matter, and the wounds then granulating up from the bottom. So long as the free escape for the pus is provided for, the course of cases treated in this way is usually favourable, and if healing take place, it is needless to say that the condition of the limb is more favourable for walking than after excision of the ends of the bones. This free incision at both sides of the joint may be often followed with advantage by free

scraping away of the diseased tissues with sharp spoons, which will much assist nature in getting rid of the products of necrosis, either in the bones or soft parts.

Finally, it may be noted that, if any joint in the body offers greater opportunities than another for testing the value of the intra-synovial and inter-osseal injection of carbolic acid solutions, as recommended by Hueter (p. 343) for strumous disease, it ought to be the knee, all parts of which are so easy to reach with the needle, and are so open to observation after the operation. The method deserves a fair trial.

Syphilitic affections of the knee-joint offer no special features for particular description. It need only be said that they may present themselves in infancy, in youth, and more rarely in mature life. Those met with in infancy are usually the forms of epiphysitis already described (p. 353), due to the hereditary taint. This form is only met with in infancy, and is not difficult to recognise. The first point noticed will probably be a disinclination on the part of the child to move one of the knees. The latter will be kept at rest, while the other is freely moved about. There will be little or no suffering apparently, and no special subjective symptoms. But an inspection of the knee will show that all is not right. At first there will be nothing more than slight swelling without redness over the lower end of the femur and upper end of the tibia. The joint-surfaces will appear intact, and passive movement of one over the other will cause no pain, if gently applied. A little later the swollen spots will be found to fluctuate, and probably now there will be pain, with possibly evidence of separation of one or other epiphysis. This will consist, if the femur alone be diseased, in slight deformity of the knee, the epiphyses being drawn backwards with the upper end of the tibia, and the lower end of the femur projecting forwards more or less. If both bones be diseased, there may be in addition to this some displacement of the tibia also. Besides this, careful lateral movements will often elicit free crepitus between the shafts and the epiphyses, while moderate flexion of the joint-surfaces will not do so. Then there will be complete loss of power in the limb, which will lie as still as if paralysed (Parrot, *vid. sup.*)

The syphilitic affections met with in youth in the knee are merely the expression of the deposit of the usual granulation-tissue in the soft tissues of the joints or the bone ends. When the synovial and capsular structures are alone affected, the joint will not be so evenly swollen as in the strumous affection; it will have a more uneven or lumpy look, though otherwise very much in the same condition as if affected with strumous synovitis. It requires practically the same treatment locally as the strumous form of the disease in its earlier stage of deposit, combined with the usual antisymphilitic remedies. It is a remarkable fact about this condition that it appears to give rise to very little pain or discomfort, even when marked in the synovial structures, the patient being able to walk very well on the affected limb.

The syphilitic affections of adult life, on the other hand, may be either the transient inflammatory affections of the synovial membranes met with in the earliest stages of the acquired affection, already described (p. 341), which are usually accompanied by some effusion, or they may be of the nature of diffused gummatous infiltration of the synovial structures or bones, or actual concrete gummata in one or other part of the joint structures undergoing some of the changes to which these deposits are liable. Lancereaux's¹ conclusions led him to the belief that these neoplasms differed neither in colour, consistence, nor histological composition from syphilitic deposits elsewhere in the subcutaneous tissue or the viscera; also that the knee was the joint most frequently affected with this form of syphilis. This is the joint, too, in which I have mostly seen the disease.

Gout of the knee presents no special features peculiar to the joint, and requires no particular description beyond what will be found at p. 343.

Arthritis deformans (p. 344) is very frequently met with in the knee, and is a source of much trouble to those affected with it, although not so crippling in its effects as when seated in the hip. The pain in the joint is chiefly felt in the morning, and is soon followed by limitation of movement. When examined now with the hand, the out-

¹ 'Des Arthrites Syph.,' *L'Union Méd.* 1873, No. 88.

line of the joint may appear lumpy around the borders of the encrusting cartilage. During flexion and extension, too, a peculiar crackling may be felt by the hand of the surgeon and by the patient, in the earlier stages, due to the rubbing of the uneven cartilaginous surfaces one over the other. Later, the distinct grating of bone against bone can be easily felt. When eburnation has taken place, the movements of the joint may once more be pretty free, the polished surfaces rubbing one over the other with but little friction, but before this has been completed, much cutting and scoring of the apposed bones has taken place. Sometimes, however, the softening process found in the earlier stages of the disease lasts long enough for the tibia to be much altered in shape by the pressure of the femur, which generally suffers less. Thus we may find the latter nearly or actually buried in the former, with much osteophytic deposit around. Unlike the other affections of the knee, already described, there is here but little tendency to flexion as the process advances. The latter is a slow degenerative one, and causes but slight irritation of the capsular structures.

This is one of the joints in which *arthritis deformans* is occasionally accompanied by suppuration, perhaps, indeed, more frequently so than any other. This phase of the complaint is usually met with in younger patients than those we are familiar with as typical subjects of *arthritis deformans*. Indeed, the question often suggests itself in examining such cases whether we are not perhaps dealing here with a hybrid disease, as it were a mixture of struma and *arthritis deformans*, or perhaps syphilis and the latter. For, occurring thus in younger individuals, the affection presents many points of resemblance with strumous disease, without forfeiting, however, its primary characters. Again, patients who have developed the softening species of *arthritis deformans* in its typical form, other joints besides the knee presenting the characteristic nodular enlargements, may recover from the actual suppurative phase of the disease, only to die shortly after of typical tubercular disease, no new ætiological factor having presented itself in the meantime. Of this I have recently had a striking example.

The fact that the knee is the joint most frequently attacked with the suppurative form of *arthritis deformans* is perhaps explained by its exposure to so many external influences. When this change does take place, it is usually an insidious one. The symptoms of its onset are not very well marked, but are sufficiently so to make a diagnosis with tolerable certainty. Superadded to the condition already described, we now find slight heat of the part, with dusky redness, usually at either side of the knee over the head of the tibia. Underneath these there will be a sense of doughiness to the touch, hardly amounting to fluctuation. If the condition advance and further softening take place, true fluctuation may be felt, and the collection of soft material may even gradually work its way to the surface, and discharge there in the form of whitish curdy or cheesy debris. In other cases such a collection may make its way into the soft tissues around the joint, and form a large cold abscess, as I have seen in a very marked case. All this time there may be little or no inflammatory reaction in the knee, and but little pain unless on motion, even in extreme cases, the whole process being little more than a degenerative one. But when an accumulation of this kind has been left to itself to burst, or has been opened without due antiseptic precautions, sooner or later the part is almost sure to become foul, and then we shall find a discharge of true pus, replacing the curdy material, and with this change all the evidences of active inflammation. But such external openings do not always form, and a reparative action may set in under careful local and constitutional treatment in the direction of improving the vitality of the tissues now degenerating. If this be the case, more or less complete ankylosis may take place, which, as already stated, is very exceptional with *arthritis deformans*; here it is only possible as the result of suppurative destruction of the joint surfaces. But in this last case actual synostosis may take place, unlike the simple mechanical locking of the parts so often seen in the usual form of the affection.

In considering the question of treatment, the first point to be noted is that very much more may be accomplished by improving the general health and vitality of the body than by any local treatment. The best we can do in the latter direction is to

guard the knee from cold and damp, by covering it with cotton-wool or flannel, and to employ systematic friction, with or without stimulating liniments. In the earlier stages the part should not be immobilised, and the patient may be encouraged to take exercise, so as to encourage active circulation. Later on, when the ends of the bone are in a softened condition, if there be any tendency to deformity, the knee may be supported by a splint of leather or wood, and exercise need not be interdicted if the patient can bear it. But when actual liquefaction is taking place, the most complete immobilisation is desirable. This is perhaps best compassed by the plaster of Paris bandage applied over cotton-wool, though the starch bandage also is suitable and lighter. But whatever is applied should be portable by the patient himself, and enable him to take exercise on crutches, which is essential if the part is ever to be repaired. In those rare cases where the disease advances to liquefaction on a large scale, and the joint ends are bathed in broken-down material, the question arises whether incision and drainage, or complete excision, is the most suitable treatment. Premising that no cutting operation is desirable in such cases, unless as a last resource, and where the collection is about inevitably to burst, it may be said that probably both procedures have their place. But, considering the age at which this disease usually becomes extreme, and the general lack of vital force of which it appears in many cases to be merely the expression, we cannot hope for much from either, the prospect of repair being so slender. Nevertheless cases are met with from time to time in which there appears to be nothing left but one or other, the joint being completely disorganised. In some of these, especially where the bones are less involved, free incision and drainage will do all that can be done for the joint; in others, where there is already much destruction of bone, it may possibly save some time if the joint be freely opened and the ends sawn off. But up to the present, excision has not been looked upon with favour for this disease, and has been very rarely practised. Mr. Gant¹ has recorded a case, however, where he excised the knee of a woman past middle life, for an affection which he regarded as probably arthritis deformans, and with a favourable result. Mr. Curling² had already placed a similar case on record in 1869, which is alluded to by Mr. Gant. Mr. Holmes, too, has told me of another case, in which this operation appeared to hold out the best prospect to one of his patients suffering plainly from this disease, and where the event justified his conclusion. It seems likely, however, that in the future, incision, with free scraping of the diseased surfaces with a sharp spoon, will take the place of formal excision, and save any cases which are to be saved from amputation, which is all that is left if repair of the bones does not take place.

Sometimes arthritis deformans gives rise to the production of outgrowths either from the synovial membrane, cartilage, or bone, which form pedunculated masses liable to be broken off, forming *loose bodies*, as already mentioned (p. 345).

This leads us to consider the mode of removal of *loose bodies* from the knee-joint, whatever be their etiology, a question which has been already considered (p. 357). And, first, it may be pointed out that, if there be many such present, it is not desirable to attempt their removal at all. Not only would there be a difficulty in doing this, but we would probably, in such a case, be dealing with a joint in a very distinctly diseased condition, which would be most likely to reproduce such bodies again under the extra stimulus or irritation of an operation, however carefully carried out. It is only, then, when we have a small number to deal with that we attempt to free the articulation of them. This is best done by the direct method of incision, which is undoubtedly the most certain to effect what we want, and which in these days of antiseptic surgery has but few risks. The mode of procedure is as follows:—The loose body being fixed at one part of the joint (usually best over the external condyle) and firmly held by the fingers of an assistant, pressing it against the synovial pouch wall, the latter is cut down upon by one or two firm cuts with a sharp scalpel and through by cutting on the loose body. When the incision is free enough, and the latter quite unattached, it slips out usually with a sudden jerk, and the operation is finished, unless there be more than one. If so, and it do not present itself at once, the joint may be

¹ *Trans. Med.-Chir. Soc.* vol. lvi. p. 213.

² *Lancet*, 1869.

carefully explored by passing the finger in through the opening, and then, when the other body or bodies is found, coaxing it with this and external manipulation towards and out of the opening. If, on the other hand, the loose cartilage be attached at one end, it must be drawn out of the opening with hooked forceps, and cut away at its pedicle. The wound may then be drawn together with a stitch or two, leaving a short piece of drain-tube in it for a few days, in case of effusion. But, if the whole operation have been conducted on strictly antiseptic principles, there will be little to fear from this, and in the simpler operation it is better to dispense with the drain-tube, leaving in at most a few horse-hairs. If, however, any unfortunate contamination of the joint should take place, and acute suppurative inflammation supervene, the part must be treated on ordinary principles (p. 335), always remembering that early and effectual drainage by incision is the first consideration. After the removal of the loose bodies and application of the antiseptic dressing, the limb must be kept at perfect rest until the external wound is healed, when it may be gradually exercised, first by passive then by active movement.

The indirect method, which is less employed for the removal of loose bodies from the knee now than formerly, has been already described, as far as is necessary (p. 358).

We have now to consider briefly another condition of the knee, which produces symptoms closely resembling those present in the last affection. This is that luxation, or subluxation, of one or other semilunar cartilage not unfrequently met with. It is not very easy to account in all cases for the occurrence of this lesion, but in others it is plainly due to some sudden and unexpected wrench of the joint. The evidence of its existence is as follows:—The patient, after some sudden and unusual twist of the knee, may be seized with a most agonising pain in the part, which he is now unable to extend fully and fixes in the flexed position. It remains thus fixed often for several hours, until the pain generally subsides, and the limb extends, when the joint may appear as well as ever, after a short period of stiffness or soreness, and perhaps trifling effusion. But sooner or later such attacks recur, often over and over again, with increased frequency, the patient becoming more or less crippled in consequence. If, during the stage of flexion and fixation, the joint be examined, the border of the displaced meniscus may often be felt thrust outwards against the capsule. What has occurred in these cases is this: the looseness of the semilunar cartilage has enabled it to slip between femur and tibia where the joint is flexed, but in an unusual way, so as not to slip out of the way during extension. The consequence is, that it becomes nipped tightly between the two bones, which, as extension is completed, are held apart by it, thus putting all the more tense ligaments of the joint on the stretch, and causing the pain complained of. The latter is similar in character, but not so severe in degree, as that present with loose bodies.

In the treatment of this condition, two points have to be considered: first, how to overcome the fixed flexion of the knee and restore the meniscus to its normal position; second, how to prevent recurrence of the luxation. In reference to the first requirement, it may be frankly said that we have learned something from the so-called 'bone setters.' Their blind wrench to straighten the limb has been so often followed by complete reduction of the cartilage at once, and restoration of the movements of the knee on the spot, that this treatment of forced extension, intelligently applied, has come into regular use. In a given case, then, where the knee is fixed in flexion, the patient should be put under the influence of an anæsthetic; the surgeon then grasping the ankle, with his right hand, and placing the left on the affected knee, should make forcible sudden extension (after momentary increase of the flexion), when the cartilage will be found to slip into its place. After this, the patient will be able to walk, but should rest the joint for a day or two while soreness remains.

The next point to be guarded against is the slipping out again of the meniscus, during some sudden movement of the joint. This is prevented to some extent by the use of an elastic kneecap or bandage, which, by supporting the capsular structures around the semilunar cartilage, may serve to retain it in position. But very often this is inadequate, and attacks recur like the first, probably owing to a relaxation of

the ligamentous structures, which hold the meniscus in its place. All that can be done in such cases, then, is to employ firm support for the knee as before, and in addition blistering, friction and douches. In some cases the capsular structures become very loose, indeed, with this condition and, as in the case of a young girl under my care some years ago, the lateral ligaments may become so stretched as actually to allow lateral rocking of the femur on the tibia. Such cases require very firm support indeed.

AFFECTIONS OF THE ANKLE.

The affections of the ankle to which we now turn require but little special notice on the whole. The most common are simple synovitis and strumous disease; and although the pyemic, syphilitic, gouty, and chronic rheumatoid are often met with, they present no features here peculiar to the ankle-joint which need detain us.

From its exposed situation this joint is very liable to simple synovitis. This is ushered in by a little uneasiness and stiffness for a short time, succeeded by acute pain on movement, with local tenderness and redness. The part is at the same time swollen, the swelling being most marked over the sides of the joint in front of the lateral ligaments, where also fluctuation may be quite distinct. The ordinary position of the joint is not altered much in this case; but, if anything, the foot is a little pointed; it is, however, fixed, and active motion is avoided, passive being resisted.

The treatment is that described as suitable for synovitis elsewhere. But here we have no difficulty in giving the part rest, if need be, without preventing exercise—namely, by placing the limb on the affected side on an ordinary wooden pin or leg reaching from the knee, upon which he can walk about while the foot is at perfect rest.

The sub-acute and chronic forms of synovitis, as well as those due to sepsis, need no special description here.

Strumous disease presents the same general features here as in other joints. It may commence either in the ends of the bones, or the synovialis, and run the same course, as already described. If starting in the end of the tibia, there appears little reason why it should not be early recognised, and treated by removal of the diseased bone, by scraping, before the inflammation has spread to the joint proper. The swelling in the synovial form is most marked at either side of the joint in front and behind the lateral ligaments, and has the usual elastic feel to the finger.

If the affection run on, and degeneration of the pulpy tissue take place, with the formation of fistulae, these will also usually be found on the lateral aspect of the articulation, either in front or behind the tips of the malleoli. But before this has taken place the disease will, in many cases, have spread to the other articulations of the foot contiguous to it, and the original affection be masked by the newer changes. This is one of the reasons why excision of this articulation has, up to the present, been so sparingly practised in comparison with that of other joints, and amputation through the lower end of the tibia has been preferred, where the ankle joint was diseased. But the more accurate knowledge of recent years as to the mode of the origin of the affection, and the improvements in the modes of wound-treatment, have worked a change here, and surgeons are beginning to look with more hopefulness upon the future of excision of the ankle joint, and to perform the operation more frequently. Still there are not yet many who would quite endorse Professor Hueter's dictum when he says that 'the indications for excision of the talo-crural articulation have come when, together with synovitis granulosa, suppuration has declared itself.' In this country we are still inclined to rely in such a case rather upon free incision and drainage, with possibly scraping out of the diseased tissue with a sharp spoon, with careful antiseptic precautions, than upon any formal excision.

AFFECTIONS OF THE TARSAL AND METATARSAL JOINTS.

The diseases of the tarsal and tarso-metatarsal joints require no special description. They present no features differing from those of other joints, whether

they be simple, inflammatory, pyæmic, strumous, syphilitic, gouty, or rheumatoid. It is, on the whole, rare to find one of them exclusively affected, though such a condition is not by any means unknown, and may be met from time to time; as, for instance, in the calcaneo-astragaloid. This is not only due to the fact that several of the joints communicate by one common synovial membrane, but also that they exist under the same constitutional conditions, and are exposed to the same external influences all together. Here, as elsewhere, we find the morbid processes starting either in the synovial tissues or the bones, and perhaps also rarely in the ligamentous structures. But, wherever the starting-point is, there is a tendency for it to spread soon to all the structures around, until all are involved in the common change. When the disease starts in one of the smaller bones, however, it may possibly advance more rapidly towards a surface away from any of its articular facets, and show symptoms of its presence on the surface of the foot comparatively early. It is in such cases that we should look out for, and treat early; for here we may be able to save the whole foot. Here we may choose either the excision of the whole bone, if we believe that the congestion starting in the small bone has already spread to the synovial structures of contiguous joints to a dangerous extent; or, we may be content to cut down upon the bone, and carefully scrape away the focus of disease from

FIG. 83.—Disease of the Tarsus, commencing in the joint, between the os-calcis and astragalus. (From a preparation in the Museum of St. George's Hospital.)

its centre, without trespassing on its surfaces, if these are found healthy. In some cases it is possible thus to scrape away almost the whole bone, leaving only a thin shell underneath the periosteum and encrusting cartilage. If free drainage of the resulting cavity be now provided for, and the part be kept perfectly free from all septic contamination, the hollow may fill up with healthy granulations, and these undergo fibrous or osseous development, until the whole bone becomes solid again. These operations of scraping out diseased bones are practically equal to sub-periosteal resections, as they are called, and afford better results, if carefully planned and conducted at an early stage of the disease, than any formal resection, as long as the bone alone is diseased. But, if the synovial structures are extensively involved, it is perhaps better to resort to wider removal, and to remove too much rather than too little. But here, too, in some early cases, free scraping with sharp spoons and thorough drainage will effectually arrest the spread of the affection. In advanced cases we shall still be called upon to perform amputation as heretofore, the prospect of reaching all the diseased structures, either by scraping or excision, being remote, and the dangers of exhaustion, general infection, and amyloid change in the internal organs being ever present. What is needed is very careful examination of the foot as early as possible, and when we are convinced that caseation is taking place in any bone or synovial tract, then free removal of that material, and even complete 'évidemment' (as it was called by Sédillot) of the affected bone, until nothing but its

superficial lamella is left, or complete riddance of the joint cavity of all diseased synovial tissue, if this be in question.

With the question of the formal excisions of particular tarsal or metatarsal joints we are not concerned here; they will be found treated of in the essay on EXCISION.

When the morbid process has not gone as far as caseation, but the rarefying osteitis or synovitis *granulosa* are present in their earlier stages, general attention to the strumous condition, with no local treatment beyond rest, is often sufficient for the recovery of the part. But that local treatment is as useful here as with other joints there is no doubt. How this should be carried out has already been generally considered. As to procuring rest for the part, this is perhaps best accomplished with those who are obliged to earn their living by providing them with a pin stump in which the knee can rest, and on which they can walk with the foot out of use for a long time. In other cases a plaster-of-Paris boot will steady the part better, while crutches will relieve the patient of the necessity of using the foot.

The only other joint of the foot which requires particular attention, and that only for a few moments, is the metacarpo-phalangeal of the great toe, the morbid conditions of which occasionally call for surgical interference. This joint is particularly liable to arthritis *deformans* and to gout, which, however, present no special peculiarities here. The treatment of the latter being generally considered as usually coming within the province of the physician may be passed over here, but it must occur to every surgeon, from time to time, to speculate whether this ought always to remain so, and whether the painful gouty disorganisation of this joint, as well as that produced by arthritis *deformans*, might not be met by a free excision or incision in the scraping out of the diseased structures. Hitherto this has been regarded with no favour in view of the diathesis which seems to interfere with proper plastic processes. But with our improved means of operation and wound-treatment in the present day, it is possible that we might obtain results far better than would have been hoped for some years ago, and with far less risks to the patient.

The last condition to be alluded to is that produced in this joint by the use of ill-shapen shoes or boots which force the great toe into strong abduction and retain it thus. Where such perverted position has been maintained for long periods, the toe may give rise to much discomfort in walking by coming to lie either over or under the adjacent ones. The head of the metatarsal bone then forms a projection on the inner side of the foot, uncovered by the base of the phalanx, which is partially dislocated inwards. Very often the prominence thus formed becomes covered by a bursa which protects it somewhat. But sooner or later this bursa is apt to inflame, and, if so, becomes a source of much discomfort to the patient. In this state the ordinary treatment of adventitious bursæ may be sufficient, *i.e.* removal of the exciting cause, local antiphlogistics, incision and drainage, or excision of the offending sac. But very often the inflamed bursa will ulcerate into the joint as well as towards the surface, and in this case something more must be done. Probably the best treatment under these circumstances is to resect the joint with the bursa, and allow the two bones to unite in good position, thus effecting two very desirable objects: one, the removal of the cause of suppuration; and, secondly, the restoration of the toe to a straight line with the foot. But, even in those cases in which no suppuration exists either in the bursa or joint, but where the abducted toe is interfering greatly with the patient's comfort in walking, excision is quite justifiable. It must be remembered that the class of patients who usually suffer in this way can ill afford the time and expense necessary for a prolonged treatment by any of those ingenious orthopædic appliances for straightening the toe, such as have been designed, for instance, by Pitha and others. Under these circumstances excision of the head of the metatarsal bone has been practised with the best results by Hamilton, Rose, Hueter, and others. It is a simple operation, and can be performed without injury to the tendinous sheaths, a danger we cannot be too careful to avoid. A straight incision on the outer side of the joint, in the direction of the metatarsal bone, gives access to the head of the latter, which can then be removed by saw or bone forceps. The phalanx is then brought straight, and is retained thus on a splint, with

an antiseptic dressing over all. If the healing process run its course undisturbed, as it probably will do if the strictest cleanliness be observed, the result is a source of great comfort to the patient.

Corresponding deformities of the smaller toes, if present, are perhaps best dealt with by amputation if productive of great discomfort. Such a deformed member is of little importance to a patient, and its removal can in no way interfere with good locomotion.

AFFECTIONS OF THE SHOULDER.

Turning now to the upper extremity, we find a very plain repetition of what has been noticed in the lower, the same diseases leading to analogous results.

Taking the shoulder first, we have a simple synovitis in its various forms, pyæmic synovitis in its several varieties, strumous and syphilitic disease, and that known as arthritis deformans.

Of *simple synovitis* of this joint, it need only be remarked that, in addition to all the subjective symptoms of the affection already enumerated, there are a few objective peculiar to the part in question. First, it must be noted that fluctuation in this joint is not so easy to discover as in others, on account of the thick covering of muscle which envelops it. On its axillary aspect we may, however, detect fulness when the arm is slightly drawn away from the side. But, even without this, we can determine the presence of synovitis in other ways, and especially by the fixation of the scapula to the humerus. The latter is so freely movable on the former, and this on the trunk normally, that deviations from this norm are more easily detected. In the case of the shoulder, there is no distortion of the joint with synovitis; that is, no one part of the inflamed capsular structure requires to be relaxed for its relief more than another. All that the patient is anxious to do here, and does from the first involuntarily, is to fix the joint. In such a case the arm may perhaps be brought fairly well from the side, by the surgeon, without producing pain, or carried forwards or backwards, and at the first glance the joint might be thought free. But, on placing the hand on the scapula, it will be found that all the motion is through its free play upon the ribs, moving with the humerus. If it be fixed with the hand, and an attempt be made to move the arm in any direction, the latter will be found fixed, and pain will be produced. If, on the other hand, the humerus can be rotated freely while the scapula is held immovable with the hand, the subjective symptoms present are not those of synovitis; with immobility of the joint they can mean nothing else in recent cases.

In the treatment of the affection here we have less difficulties to contend with than elsewhere. The joint holds the same position, whether inflamed or not, and is maintained thus at rest with comparative ease by simply placing the forearm in a sling. It is easily accessible for local treatment, such as already advised (p. 335), and whatever is done in this direction, the patient is able to enjoy all the benefits of fresh air and exercise all the time. But, if adhesion remain between or about the surfaces, difficulties in restoring motion are met with in the shoulder which are not present to the same extent in other joints. These are due to the mobility of the scapula, which, when we attempt to make passive motion, for the stretching or tearing of the new material, moves with the bones, and we have no '*point d'appui*' as in other joints. But the difficulty can to some extent be overcome if the patient be put under the influence of an anæsthetic, by giving the scapula into the charge of an assistant, who stands at the side of the patient opposite to the affected joint. If now while he grasps this bone with both hands, and fixes it against the ribs with his fingers on its borders, the humerus be slowly brought away from the side, and then rotated on its own axis, the adhesion may be gradually loosened after one or two attempts if the assistant be able to hold the scapula firmly. Unfortunately, the patient himself will not, as a rule, carry out active motion carefully. He may think that he is doing so, but the instinct to fix the painful part, and the mobility of the shoulder-blade, lead him rather to move the latter with the arm than the arm on the latter.

The *simple sub-acute* and *chronic* forms of the disease here require no special description after what has been said above.

Strumous disease is, on the whole, not so common in the shoulder as in the lower extremity. There are probably many reasons for this, among which the following may be mentioned. The joint is less exposed to atmospheric changes than either the knee or ankle, being usually well covered with clothes, as well as by the thick deltoid muscle; its circulation and the consequent vitality of its tissues are maintained thus more evenly than in these joints. And, though the shoulder is exposed very frequently to violence of greater or less degree, it must be remembered that the great mobility of the scapula secures it from the evil effects of this to a large extent. A blow upon the shoulder is spent in forcing the scapula in one direction or another, rather than in damaging the articular structures. In the case of the hip, which is equally well covered by muscle and clothing, this is not so, any jars on the trochanter or the lower limb falling notably on the joint, with the resistance of the firm pelvis behind it.

But the affection is by no means rare. When it does develop, it is *usually* in the synovial tissues, here in the first instance, and if the bones become diseased, it is secondarily. This is possibly accounted for by the fact that in this joint the exposure to strain or injury upon the epiphysial tissues is reduced to almost nil by its mechanical construction. The first symptom will be uneasiness in the joint, and presently stiffness, the scapula and humerus moving as a whole. The entire shoulder then gradually becomes swollen, with the same general subjective and objective symptoms in a sub-acute degree, to those we have seen to be present in the simple form of the affection (p. 334).

Of the treatment of this disease, both constitutional and local, little special need be said, except that, from the position of the parts, it is perhaps more easy to deal with locally than other articulations, rest being easily secured in good position. Even when it becomes much disorganised, by softening and suppuration, there are less difficulties connected with its efficient and antiseptic drainage than elsewhere. The point usually chosen for incision, where drainage, with or without free scraping out of the diseased tissues, is desired, is in front, along the inner border of the deltoid muscle, where the inflammatory matters present. Sometimes, however, they point behind, and may be removed by a vertical incision. Occasionally, however, the articulation does become so completely disorganised as to call for resection or amputation (see 'Excision' and 'Amputation').

Strumous disease of this joint may also arise in inflammation seated in the epiphysis of the head of the bone, for the special description of which the reader is referred to the special paragraph on 'Epiphysitis' (p. 353). In the early stages of the latter affection the diagnosis is easily made on observing that the movements of the joint are perfect and painless, while the head of the bone is tender on pressure, or on being struck on the elbow; but later on there is much difficulty in the matter, owing to the fact that the disease, if it reach the periphery of the epiphysis, must almost necessarily invade the joint, the growing line lying within the capsule. It may, however, spread towards the shaft, and eventually reach the surface of the bone external to the capsule, the joint being thus saved.

In early infancy there are, it should be remembered, several forms of epiphysitis at the head of the humerus, which may be the starting-point of disease in the shoulder-joint, although they do not in all cases *necessarily* involve it to any extent. These diseases, arising from injury, infantile pyæmia, struma, or syphilis, have been already alluded to (see 'Epiphysitis'). It is only necessary to add that they should be looked out for carefully here, for it is quite possible that in the future a more rapid and certain diagnosis, the result of familiarity with the diseases, may enable us to treat them at a stage when the joint may be saved from those disastrous changes so often met with from spread of the morbid condition to its surfaces not originally implicated.

Another affection, sometimes taken for trouble in the joint, is inflammation of the bursa under the deltoid. A careful examination, however, of the other aspects of

the articulation, taken with the history, and the painless motion in the joint, serve to distinguish the two conditions from one another.

Arthritis deformans is met with very frequently in the shoulder, and may lead to great fixation of the joint, and enlargement; but the disease presents no peculiarities here which call for special description.

This joint is not unfrequently the seat of *septic synovitis* in any of its forms (p. 337) which will present the same features here as elsewhere. These affections hardly require, therefore, any special description, and their treatment will be carried out on the principles which have already been considered (p. 339).

AFFECTIONS OF THE ELBOW.

The elbow-joint, now to be considered, is very frequently the seat of disease, usually of the inflammatory type. Its functional activity and exposed situation would lead us to expect this. Still it appears to be less often diseased than its analogue, the knee, probably on account of the scapular mobility acting here, as it were, as a buffer during any violence to the arm.

Simple acute synovitis, as exhibited in the elbow, is accompanied by a considerable alteration in the usual form and position of the joint. On the front little or nothing is noticed, but on either side of the olecranon, behind, and over the head of the radius, there is considerable fulness, and even fluctuation, and the part is held in a position of slight flexion and half pronation. Any attempt to alter this is accompanied with much pain. Except in very acute cases, there is not much general redness of the whole circumference of the joint. The diagnosis can hardly give much difficulty, the disease being unlikely to be mistaken for anything else, except perhaps acute inflammation of the bursa over the olecranon. Here, however, the rotation of the radius will be unaffected, and though flexion to any extent may be resisted, what motion there is does not produce pain in the joint.

The treatment is conducted on the general principles noticed (p. 335), and as rest is easily secured for this joint, is easier to carry out than in many other situations. The forearm should be flexed to a little less than a right angle, and placed on a splint or in a sling with the hand in mid-pronation. The joint itself can be left exposed for any applications that may be thought necessary (p. 335). If these be applied with judgment, and the patient be ordinarily robust, the prognosis is good, the joint before long recovering completely. If not so, the affection is apt to become chronic, and then we have often an organisation of plastic matter gradually effused into and around the joint, with resulting stiffness, if not actual synostosis. The treatment of this latter condition, after all inflammation has subsided, depends upon the position in which the limb has become fixed. If at an angle somewhat less than a right angle, and so that the different parts of the hand can be reached with the hand, it is perhaps well in many cases to be satisfied with the stiff limb, which will always be very useful. If, on the other hand, the limb be fixed at an obtuse angle or straight, it will be so awkward and comparatively useless that excision of the ankylosed joint, and the formation of either a false movable one or re-establishment of ankylosis at a proper angle, is called for. But the latter result is not usually aimed at in these days of carefully conducted excisions. But, if the fixation is merely due to some moderate degree of adhesion about the articular or peri-articular surfaces, the joint may be rendered useful again after all signs of inflammation are gone, either by sudden breaking down of these adhesions under an anæsthetic, or, by gradually stretching them or rubbing them away by constant passive motion.

Of *simple sub-acute* and *chronic synovitis* of the elbow little need be said here, the first differing only in degree of symptom and effect from that form of disease just described, the latter presenting but few points of difference, except as to ætiology, from the *strumous* form which must now engage us for a few moments.

This affection is a very common one for the same reasons that it is so in the knee (see p. 378). It usually appears to commence here in the synovial structures, more rarely in the bones, so far as we know. It may be, however, that closer study in the

future will show the bone to be more frequently the starting-point than has been generally supposed hitherto. Be that as it may, before the disease has been long in the joint, the bony surfaces of the latter become involved, and can be felt to grate more or less one upon the other. It may be necessary to place the patient under an anæsthetic in order to ascertain this, but not always, for the change is not an acute one as a rule, and the synovitis present produces but moderate tenderness. The limb will usually assume the same position as in the simple affection (see *sup.*) and present the same appearance, except that, instead of any redness, it will be usually uniformly pale and perhaps glazed. The symptoms here will not differ materially from those mentioned as present in other joints. The granulation-tissue is liable to undergo the same changes, leading to suppuration and sinuses, as elsewhere, and these openings will form on any aspect of the joint. It does not follow, however, that they shall penetrate the latter: very frequently softening goes on outside, and the fluid matter formed escapes through holes in the skin, without making its way into the articulation at all. When bone begins to be involved, it is not usually difficult to discover which of the three forming the joint is the starting-point, by close attention to history and symptoms. The rotation of the radius upon the outer condyle, for instance, is often found perfect, without roughness or grating, while the latter are perfectly clear on flexion and extension. Again, if the ulna be alone implicated, the swelling will be more marked over its extremity than over the end of the humerus, and *vice versa*.

Of the treatment of a well-marked case of strumous disease of the elbow little need be specially said here. Surgeons are more and more inclining to the belief that early excision is the proper practice for such cases where the bone is involved. When they recover without operation it is usually only after a long time, and usually with a stiff joint. When recovery takes place after excision, the worst result is a likewise stiff joint, but the repair is more rapid than in the previous instance. On the other hand, in a large proportion of cases (larger than where excision has not been performed), an excellent result as regards movement and strength is achieved. Incision or drainage is not in favour here. In the milder cases, the general or local treatment mentioned already (p. 343) will be sufficient, and with care the joint will retain its mobility; but where the disease is once well marked, excision holds out the best prospect to the patient.

The *pyæmic* affections of this joint, though common, need no particular description, as their features are those already studied in other articulations (p. 338).

Arthritis deformans is not infrequent here. It presents no points requiring special notice, however. The symptoms are the same as elsewhere; weakness and limitation of movement being most complained of. For treatment see p. 347.

It should be remembered that next to the knee this is the most frequent habitat of those loose bodies, the ætiology and treatment of which have been already considered (p. 355). The incision for their removal here should be made on the outer aspect of the joint.

AFFECTIONS OF THE WRIST.

In the wrist-joint the affections most usually met with are the simple acute, the gonorrhœal, and the strumous synovitis; arthritis deformans is also encountered occasionally, especially in females, but is not very common. But when the wrist-joint proper is affected with any of these changes, the adjacent carpal articulations are usually included likewise. In most cases, however, it is for practical purposes unnecessary to distinguish between these synovial tracts, and we may now consider them altogether.

Acute synovitis is perhaps productive of more pain here than in any other articulation in the body, owing apparently to the fact that the joint or joints are naturally so difficult to immobilise, and that the whole hand is so highly organised. The swelling and redness are most marked on the dorsal aspect of the wrist, which is fixed in a slightly flexed position. Any attempt to move the part produces very acute suffer-

ing. At the same time, in uncomplicated cases, the fingers can be flexed and extended without pain. But not uncommonly the sheaths of the tendons passing over the wrist are more or less inflamed too, and in this case the whole hand is fixed. This is more often met with in the pyæmic or gonorrhœal form than in the simple. The stiffness remaining after subsidence of the inflammation in the first case is usually not great, but in the latter, where the sheaths have been implicated, is very marked, and inclines to resist treatment in a stubborn way. The latter is based upon ordinary principles, with the addition of gently increasing passive motion as soon as ever the patient can bear it.

When *strumous* change affects the wrist or carpal joints, the disease usually appears to start in the synovial structures, and generally runs its course to destruction of the surfaces of the articulations before long. Undoubtedly, however, the bones, too, are often the seat of the primary disease, which spreads to the surfaces in the usual way from the growing points. As in simple synovitis, the alteration of shape is best seen on the dorsal aspect, where the usual elastic white swelling is found, the position of the hand being that of slight flexion. Here, however, it is, on the whole, rare to find the sheaths of the bones involved, unless the condition be far advanced, and even so the fingers may often be moved freely without any pain. I have at present under my care a case of a young woman in which the wrist is enormously enlarged, with free grating in the joint, and yet the patient feels no pain in using the fingers freely. Not unfrequently, when the disease is seated in the bones, and softening takes place, the products of the process are discharged through the dorsal skin, and neither involve the joints nor the tendon sheaths in the first instance. Such cases should be watched and treated carefully, lest the articular surfaces should become secondarily involved.

Beyond the ordinary treatment for struma, nothing special is called for here in the simpler cases; but where the bone is slightly affected, incision and free scraping away of the diseased tissues will probably arrest the spread of the morbid action. Many cases recover, complete rest being easily obtainable and access to the part for local applications being free. But in a certain proportion of cases, extensive disorganisation of the joint surfaces takes place, and the choice between excision and amputation is forced upon us.

Arthritis deformans is met with in the wrist-joint, but, as a rule, only when several of the other joints of the body are similarly affected. The affection is said to be more frequent here among females than males. It calls for no further special comment (see p. 347).

The metacarpal and phalangeal joints are sometimes affected with the diseases we have been considering above, but require no special consideration, either as to ætiology or treatment.

Of the remaining diarthrodial joints not already considered, *e.g.* those of the vertebra, ribs, jaw, and clavicle, it may be said that, though they may be undoubtedly affected with the diseases we have been considering, especially with the various forms of septic synovitis and arthritis deformans, there is little special in the mode in which they are involved.

AFFECTIONS OF THE TEMPORO-MAXILLARY JOINT.

The temporo-maxillary articulation enjoys, on the whole, considerable immunity from disease. There are, however, some affections to which it appears somewhat prone. One of these is arthritis deformans, which, in some cases, reaches such a pitch that the movements of the jaw are seriously interfered with, or even completely prevented. The ætiology, symptoms, and treatment of this disease here require no special discussion, being as elsewhere. It may be noted, however, that ankylosis in this case has been treated by resection of the joint (Humphrey).

The ordinary forms of synovial disease are rarely met with here, but those due to the pyæmic state are occasionally found. There is another to which very little attention has been called in books, but which I have often had an opportunity of observing,

and sometimes of dissecting after death. This is that disease produced in the articulation by suppuration in the middle ear. This is only met with in children, and is due to the presence, in many young persons, of a hiatus in that part of the tympanic plate which forms the floor of the meatus and roof of the articulation, and which is always present at a very early age, but persists sometimes as long as into adult life. This hiatus lies just outside the tympanic ring on the floor of the meatus, and if the latter, after an attack of otitis media, be constantly bathed in fetid pus, softening of the thin membrane, by which the gap is filled up, often takes place, and thus the pus gains access to the joint, producing a secondary synovitis of a most destructive form. This I have seen, and within the last month I have had a little girl under my care at University College Hospital, in whom extensive necrosis of the ramus of the jaw commenced in this way, the ear having been neglected. After prolonged treatment and several operations by one of my colleagues, the sinuses over the ramus healed, but the ear continued to discharge copiously. When she came to me recently for treatment, I could see a large piece of loose dead bone in the meatus, and on removing it by gentle traction, found it to be the condyle of the jaw entire, which had made its way up into the meatus through the tympanic plate, where the latter was destroyed. Such cases must be borne in mind as illustrating one of the many dangers of chronic otitis media purulenta.

Beyond these diseases, and that affection known as subluxation of the intermaxillary cartilage which is described in the essay ON INJURIES OF THE FACE, there is no special condition of the joint which need detain us further.

AFFECTIONS OF THE SYMPHYSIS PUBIS.

A few words now remain to be said regarding what are known as the amphiarthrodial joints. Among these it is rare, on the whole, to find disease, for reasons alluded to on p. 333, and it is only necessary to refer to the most important. Among these may be reckoned the articulations between the bodies of the vertebræ, the pubic and sacro-iliac synchondrosis. The first of these are considered sufficiently in treating of the spine (see 'Spinal Disease'); of the latter, disease of the pubic articulation is least common. In pyæmia, especially during the puerperal state, inflammation is occasionally observed, caused as in other joints, and running the same course even to suppuration. In such a case the abscess will point on the mons veneris on one side or run up the rectus muscle. It will be treated on ordinary principles.

Strumous disease of the part is also rarely met with, and will present many of the same symptoms in a milder form. It has only fallen to my lot to see one case of primary caries of the joint. This was in a young female of about 23, who came into University College Hospital with a sinus over the ramus of the pubis. She died shortly after admission, suddenly, during an attack of vomiting, and at the autopsy I found the cause to be rupture of the œsophagus. The pubic joint was quite curious, and movable, a sinus running upwards and outwards over the ramus. The cause was obscure, as a history was not obtained.

The special treatment of such conditions would consist in rest in the horizontal position, nothing short of this offering much prospect of rest for the joint, unless, perhaps, a broad plaster-of-Paris corset, including the whole pelvis, should be applicable where no sinuses exist.

SACRO-ILIAC DISEASE.

Sacro-iliac disease is distinctly more frequent than that of the last-mentioned joint, though still a rare affection, on the whole. It may be mentioned, as bearing on this point, that during the last ten years, 1871-1880, only thirteen cases of this affection have been treated in University Hospital; these, with, in addition, two cases at present in the house, constitute but a very small percentage of the mass of joint diseases treated in the same time. Among these 13 cases, 5 were males, 8 females, the ages ranging from 15 to 52, the average being 27.

The results of treatment in these cases have not been encouraging: 1 is noted as cured, 3 as having died, one of these shortly after leaving the hospital; in the two others it fell to my lot to make the post-mortem examination; 5 are stated to be relieved, 3 unrelieved; 1 uncertain, and of those cases noted as 'relieved' it is questionable whether the benefit was not merely temporary, and likely to be followed by exhaustive suppuration, as also in those marked as 'unrelieved' (3). In the cases now in hospital I have aspirated large abscesses, several times in one, and this has been repeated by one of my colleagues, the patient lying now in a very critical state.

The causation of the disease is, no doubt, at least twofold. It may originate in injury or in struma. In one of the cases mentioned above, where the patient was under my own observation from the very beginning of the ailment until death, there was no history whatever of injury, and yet the course of the disease was very rapid, the whole joint being destroyed in a few months, with extensive suppuration requiring six aspirations, the patient ultimately dying of exhaustion and phthisis. At the autopsy I found the joint quite loose, and the fibro-cartilage destroyed. This was probably a case of the true stumous disease. In other cases it appears equally clear that injury is the cause of the disease. In rare cases it is said to be pyæmic, but this I have never seen.

The symptoms upon which a diagnosis of the affection has to be based are very various, and as success in the future in treating it will be in proportion to its early recognition, we must study in the first place that class of symptoms earliest observable, namely the subjective.

The first thing complained of by the patient is usually weakness in the lower part of the back, a feeling of insecurity in walking, and of great fatigue on doing so. The next will probably be pain, but in a number of different situations. First, and very commonly, over the articulation itself, usually on its posterior aspect. This may be increased, in some cases, by pressing the crests of the ossa ilii towards each other or pushing the sacrum forwards. But this is not found in very early cases, *i.e.* just those we are most anxious to diagnose. For here it may be that only one border of the articulation is eroded (as in the second case I examined after death), the rest of it remaining as firm as ever. In such a case, pressure in the directions indicated may not produce the slightest pain. But the pain is frequently referred to the course of the sciatic nerve, or its branches. This was notably instanced in the case just mentioned, which was, indeed, treated as one of sciatica. After a time a small collection of pus was evacuated from what was supposed by the surgeon in charge to be an inflamed bursa over the great trochanter. After death, which occurred not long after, I traced this abscess inwards, along the pyriformis muscle through the sciatic notch, and then upwards, to the front of the sacro iliac joint, where it was seen to originate in a comparatively small oval focus of caries, about $1 \times \frac{1}{2} \times \frac{1}{2}$ inch in dimensions. The cause of the sciatic irritation was thus made plain. Again, the pain may be referred to the front of the thigh, through irritation of the anterior crural nerve, when the disease has reached the front of the joint. This was well marked in the first case alluded to here, where I watched the patient from the beginning and aspirated frequently. The patient complained much of pain running down the front of the thigh to the knee. Indeed, in some cases this persistent pain in the knee has led to the erroneous diagnosis of disease of that joint or of the hip. This is especially likely to take place if the psoas should be irritated by proximity to the focus of inflammation, as is occasionally found. One of the cases now in hospital illustrates this difficulty of diagnosis. It is met by observing the position of the limb, the movements of the joint, and where the pain is seated during the latter, whether in the position of the psoas or articulation; also by palpation of the latter on both its anterior and posterior aspect.

As to the objective symptoms, they are few in the earlier stages of the disease. The psoas may be a little contracted, flexing the knee slightly. This, and a slight limp, will be all that is noticed. Later on, when abscess has formed, there is more to help us; but unfortunately the disease must now be regarded as far advanced, and very grave.

These collections will present in various situations. The most common point is

behind and directly over the joint, where at first a small round abscess forms, soon growing to something very considerable. Such an abscess, if aspirated, generally fills rapidly again, and, strangely enough, sometimes with gas in large quantities. In the first case alluded to above, as treated by the author, this was notably the case, the swelling being quite tympanitic. Each aspiration also drew off a large quantity of foetid gas, before any pus came, although there was no external opening, and I always took the greatest precaution to cleanse my aspirator needle. I do not think that the gas was generated in the abscess itself, and have only been able to explain its presence by the proximity of the cæcum, lying on the front of the joint, from which, I believe, the gas was exhaled, although after death I could detect no trace of opening in the viscus itself. The passage of pus from the front of the sacro-iliac joint, along the small rotator muscles, to the trochanteric region has already been described (p. 398). In rarer cases it may pass along the iliacus muscle, and point over or under Poupart's ligament. Lastly, abscesses sometimes form under the glutæi muscles directly behind, or burst into the rectum in front.

The treatment of this affection must still be regarded as very unsatisfactory, the recoveries being, in the long run, rare, so far as we know. Rest is the first consideration. This is best secured by placing the patient in the recumbent position. And, however objectionable it may be to confine a sufferer thus for long periods, it is indispensable. For it is hard to conceive any appliance which should adequately support these joints with the patient in the erect position, the whole weight of the body being inevitably thrown upon them. If any appliance could assist in steadying the pelvis, that designed by my colleague, Mr. Christopher Heath, would probably be most likely to achieve this end. It consists in a strong girdle, which is strapped tightly round the pelvis, just above the trochanters, and provided with pads to press upon the pubis in front, and the sacrum behind. The plaster corset, brought well round the pelvic bones, would probably be of some use, too, if well fitted. But the objection to this is the impossibility of making any applications for the local treatment of the disease while the corset is in situ. Such applications would consist, in the first place, of the actual cautery, applied either in the linear or button form; then of blisters or Tr. Iodine.

Professor Hueter advocates the use here, as elsewhere, of hypodermic or intra-vascular injections of carbolic acid solutions (see p. 343). In earlier cases we may hope to do good with one or other of these remedies, alone or combined. But, as soon as pus has begun to form, they can do no good, and can only irritate our patient. In such a case all that is left to us is the removal of the pus as it is formed either by the aspirator (which is to be preferred as long as it can be used) or by antiseptic incision and drainage. In some few cases portions of carious bone may be reached through such a method, and scraped away with a sharp spoon or gouge; but the prospect in such cases is peculiarly bad. The usual result, sooner or later, is exhaustion, and death therefrom, if the patient escape the dangers of septic intoxication and its consequences.

AFFECTIONS OF THE SACRO-COCCYGEAL JOINT.

The sacro-coccygeal joint is but rarely the seat of disease, and then only as the result of injury, such as falling in the sitting posture upon some sharp ledge. It is usually met with among females, and may give rise to much suffering.

The symptoms of this affection, when acute, as described by Mr. Hilton (the author having seen but few cases), are, tenderness and heat about the joint, pain on defecation and on sitting down or rising, as well as when direct pressure is made upon the spot, or the coccyx is moved backwards and forwards between the thumb externally, and the finger introduced into the rectum. If the disease be very acute, there will also be redness and swelling over the joint, and eventually fluctuation, if suppuration be the result.

The treatment here will be free leeching in the earlier stages, followed by hot belladonna fomentations, if the disease be acute. In milder cases, too, a few leeches

will do no harm, and may cut short a condition apt to become chronic. The patient in any case should be confined to the recumbent position, and should keep the bowels relaxed by medicine and the use of light diet. At the same time the general strength should be kept up with tonics, remembering that these bones are liable to caries. If pus form, it may be evacuated into the rectum by incision on the middle line. When all evidence of active inflammation has passed off, the patient usually suffers for a long time from tenderness on sitting down, as might be expected from the fact that the weight of the body presses to a considerable extent on this joint, and strains its ligaments. This condition may best be met by the use of an apparatus consisting of two ring pads, which fit severally upon the *tubera ischii* when the patient is seated. By means of these the patient is raised sufficiently to prevent pressure upon the tip of the coccyx, and is thus able to sit with comfort. While this is in use the part may be dealt with by flying blisters or painting with tincture of iodine, tonics being administered internally, and the bowels attended to, lest the motions should at any time become hard and necessitate straining in defecation.

This affection must be distinguished from the coccydinia complained of by delicate females, possibly the result of some uterine or vaginal irritation. Here there is no local rise of temperature, and manipulation of the coccyx does not cause so much suffering, the joint being unaffected.

The treatment for this condition, with the omission of the active antiphlogistic remedies, will be almost the same, however, as in the last affection. If it fail after fair trial, especially in the direction of tonics, subcutaneous division of the ligamentous structures around the end and sides of the coccyx may be tried. This operation I have only seen once. It was, I believe, followed by some benefit.

ARTHUR E. BARKER.

DISEASES OF THE SPINE.

PART I.

CARIES OF THE SPINE.

PATHOLOGY AND TREATMENT.

IN this essay those affections of the spinal column due to disintegration of one or more of its structures will be considered, those produced independently of destructive action finding a place elsewhere in relation to 'rickets,' 'lateral curvature,' and rheumatoid arthritis. Here we have to deal with changes which in a majority of cases result unfortunately still in the deformity known as 'kyphosis' or 'angular curvature.' It is undesirable, however, that this term, indicative merely of a symptom, should be so frequently used to cover the affection which gives rise to it as is the case. The mind both of the public and our profession is thus too constantly directed to the consideration of the deformity alone, and not sufficiently to the essential nature of the primary lesion, or even quite away from the latter. The general result of this is that the disease is not so closely watched for as it should be in its very earliest stages where deformity is not yet noticeable, and, next, that when angular curvature is marked, it is often considered the most important feature of the case. It is better to speak of it as *caries of the spine*, and to study its pathology, symptoms, diagnosis, and treatment at a very early stage *before* angular curvature has resulted. The disease may be said to be far advanced when the latter is present, and should be under treatment, if possible, before it has had time to appear.

But in employing the term caries, in the sense in which we speak of it as occurring in other bones, we must carefully bear in mind that there are probably several distinct causes at work in its production, here and elsewhere. This is not the place, however, to go minutely into the question as to the relative importance of each of these factors. It will be enough if, in making use of the term here, we reserve it for the present for that affection commonly, but rather vaguely, spoken of as strumous caries. When we have considered this as it ordinarily presents itself, a paragraph will be devoted to an analogous affection manifestly due to the degeneration of syphilitic deposits in the vertebrae. In studying this condition so palpably syphilitic, we cannot avoid speculating how much of the disease commonly set down to the other causes may be due to syphilis. But beyond alluding thus briefly to these points we cannot go in an article such as the present.

Caries of the ordinary kind may commence in any of the bones of the spine from the atlas to the sacrum. But it is not found in every part of these bones to the same extent. Primarily it is limited in almost all cases to the bodies of the vertebrae, only involving the laminae, transverse and spinous processes secondarily, if at all, as a rule. It must also be borne in mind that the disease may commence independently in several of the vertebral bodies by perfectly separate foci. This is well seen in fig. 84 from a specimen removed by the author from the body of a patient who had been under his care for a long time for another disease. There are probably several reasons for the bodies being the common starting-point of the affection. First, they bear most of the weight of the trunk in all its various postures, and are thus more liable to strain or injury than the other parts of the bone. Again, the latter contain but little medullary tissue in proportion to the bodies which are more

abundantly supplied with it than any other portion of the skeleton. This preponderance of soft, vascular, connective-tissue indicates greater physiological activity than exists in the compact substance of the laminae, &c., and consequently (in agreement with the law that wherever physiological energy or growth is most active, there is the greatest proneness to inflammation), the bodies are more liable to inflammatory change than the laminae, &c.

As to which of the vertebrae are most frequently affected opinions still differ, however. Billroth states that from his own statistics the starting-point appears most often to be the sixth, and next to this the fifth, seventh, and eighth dorsal. Hueter, on the other hand, regards the last dorsal and first lumbar vertebrae as most commonly affected, and from my own observation I am inclined to regard this as nearer the truth. In fact, the disposition to disease appears to diminish as we ascend the column, morbid change being least often met with in the cervical region.

Fig. 84.—Copied from a photograph of a preparation in the fresh state, placed later by the author in University College Museum. See also 'Path. Soc. Trans. 1882.' Card specimens.

Shows early disease of the vertebral bodies commencing *independently* at two parts of the column in a young child who had always been in arms and had received no injury. Shows also that the starting point may be on the *posterior* aspect of the bodies (*a*) which could not be affected by violence without injury at the same time to the *anterior* part. The dark lines at either surface of the softening spot (*b*) indicate the inflamed area of the bone around. The anterior part of the intervertebral disk (*c*) is healthy. The relations of both the anterior and posterior common ligaments to the broken down material is well seen as also that of the cord.

In this we have only another aspect of the general law just stated. For it has been established that growth of the spine is most rapid in the lumbar region, less so in the dorsal, and slowest of all in the cervical. The same law, too, applies to the age at which inflammatory changes are met with here. In by far the largest proportion of cases (in cervical disease I believe almost *always*) these date from childhood, when, as we know, the physiological hyperaemia connected with growth is most active. Occasionally, but rarely, spinal caries develops rapidly in adults, as the result of severe injury or syphilis; but hardly ever as a strumous affection amongst elderly people. Such cases as that recorded by Dr. Ogle,¹ where a well-known gentleman,

¹ *Path. Soc. Trans.* vol. xv. p. 20.

aged 73, developed rapid and fatal caries of the three upper cervical vertebræ, must be regarded as quite exceptional. And, in the absence of further details as to previous history, &c., than are furnished in the report quoted, one would not be justified in setting the case down as of truly strumous origin. Within the first year of life, however, it certainly is not commonly seen; but after this, and up to puberty, it is one of the familiar bone affections. The earliest age, so far as I know, at which its existence has been demonstrated, was shortly after birth, the child dying five weeks later of suppurative caries of the seventh cervical vertebra.¹ In this case the parents were healthy and non-syphilitic, and had had a healthy child before. But, from observation, I am inclined to think that, in infants and young children dying of tuberculosis, carious disease of the spine, without deformity, would often be found if only it were carefully looked for by section of the column.

But, though it is well known that any part of the column may become implicated in caries, there has hitherto been some difficulty, among pathologists, in agreeing as to which structure exactly the disease first commences in. This is probably owing to the fact that the disease is mostly looked for among those who die of spinal caries, where very extensive destruction has already taken place. Broadly stated, two views are commonly put forward upon this point, and sometimes as though they were totally antagonistic and irreconcilable. According to one, the disease starts in the ligamentous structures and spreads to the bones; according to the other, it originates in the bones, and only secondarily involves the ligaments. A little consideration of the normal histology of the parts will show that apparently a misapprehension lies at the root of this different description of the disease by different observers.

In the first place, it must be remembered that ligaments are rarely or ever the seat of primary disease of any kind, in any part of the body. They consist of fully-developed connective-tissue, which, having advanced a long way from its embryonic type, is consequently but little susceptible to morbid change. Where ligaments overlie synovial membrane or bone, they may, as is familiar to us, become secondarily involved in the inflammatory affections of either one or the other, but only in a passive way. In the case of the spine this rule applies as well to the anterior and posterior common ligament as to the intervertebral disks.

On the other hand, if it is contended that the affection starts in the bone, and spreads to the ligaments, the precise region in the bone ought to be defined. If this is done, the two supposedly adverse views converge towards the same point—namely, the deeper or growing layers of the periosteum, and of the encrusting cartilage, which might be supposed to belong to either the ligamentous structures which cover them or to the bone which they cover. In reality, of course, they are part of the latter. The fact is that in by far the largest proportion of cases the inflammation originates in this growing line of the bone, *i.e.* immediately underneath its periosteum, and (where it possesses a cartilaginous covering) at its juncture with the latter. In those rare cases where inflammatory disease of the spine originates in the adult, we have probably something wholly different before us, and it would be well to keep the two groups of cases quite distinct in our minds.

Starting, then, at this naturally hyperæmic line in obedience to the laws above referred to, inflammation may, on the one hand, spread more extensively towards the ligamentous structures, or on the other towards the underlying bone. In the first case, the appearances are often supposed to indicate that the disease has commenced in the former, but in the last that it has started in the bone. As a rule, however, it spreads more rapidly into the latter, owing to its being more vascular and containing more young connective-tissue (see p. 102).

Turning now to the primary morbid process itself, which results in this caries, we must study it first in the earliest stages in which it is possible to examine it. As a rule, opportunities of dissecting this form of spinal disease very early are rare. It is usually far advanced in destructive change before the patients succumb. But among a number of dissections, we are sure to find some in which at one spot or another, more or less remote from the primary focus, the morbid process has only

¹ Hjelt, *Virchow's Jahrb.* 1871, vol. ii. p. 384.

comparatively recently commenced. Such a case, among many others, I have had occasion to dissect carefully within the last few weeks. It is represented in fig. 84, taken from a photograph of the preparation in a fresh state (see also 'Path. Soc. Trans.' 1882).—I may mention that this is a comparatively rare specimen, in one respect particularly—i.e. it shows a distinctly isolated focus of caries starting on the posterior aspect of a vertebral body, the anterior and other parts of which are perfectly sound. The same condition of things due to syphilitic disease of the spine will be alluded to presently. This could not possibly have been the result of injury, as one is unable to suppose the back of a vertebral body being injured while the front was intact.—In these cases, the first thing noticed is a hyperæmia of and adjacent to the lines of growth of the body of the bone, i.e. just under its periosteum and encrusting cartilage. This hyperæmia is in character hardly more than passive. Indeed in young bones it is here, as elsewhere, hard to say positively in any given case, when examined

FIG. 85. —(From a dried specimen in University College Museum.)

Illustrates the effects of *caries multipia granulosa* of the strumous form acting upon the front of the bodies of the vertebra and leaving the intervertebral disks intact. The latter are dried and shrunken in the specimen, but normal. The 'pitting' by pressure of bosses of granulation tissue is well seen hollowing out the bodies, and starting underneath the anterior common ligament. The surface behind (a, a) is much by a saw cut removing the transverse processes.

early, where 'the physiological' ends and 'the pathological' begins. A little later on, however, an abnormal amount of young, soft granulation-tissue is found at the points indicated. At the periphery of the body—e.g. under the anterior, and possibly, as in the case just alluded to, the posterior common ligament (fig. 84, p. 402) or again underneath the encrusting cartilage—this will eventually form a soft bed, pressing against the bone substance, and increasing at the expense of the latter, bosses of granulation-tissue projecting into the body, here and there, and forming pits in it (fig. 85). The bone proper, however, has not been quiescent all this time; its medullary substance has begun to participate in the process, and has furnished part of the granulation-tissue. To put it briefly, inflammatory hyperplasia has caused the medulla to increase at the expense of the osseous trabeculae enclosing it, which it absorbs by virtue of the vital action of its cells, aided by that of the bone corpuscles. In short, the structure is now invaded by a slowly advancing, rarefying osteitis, or, as it is also well called, an *osteo-myelitis granulosa*. That such a process may commence in the deeper parts of the bone occasionally, and spread outwards, appears probable; but that the course of the disease from the periphery towards the centre, as just described, is the rule we are taught both by experience and analogy. With the changes just described, there may or may not be suppuration. In the latter case, the condition was often spoken of by earlier writers as *caries sicca* or *fungosa*, but is perhaps now better described histologically as *rarefying osteitis* or *osteo-myelitis granuloma*. Here the whole of the body of one or more vertebrae may become slowly converted into a soft mass of granulation-tissue or inflamed medulla, with patches of caseation scattered through it, hardly a trace of osseous substance remaining; and yet all this without any pus-formation. What is now to become of this lowly-organised substance, short of its breaking down into a puriform fluid, depends upon a variety of circumstances. If the marked dyscrasia usually accompanying the local condition be early ameliorated or recovered from, a more or less complete *restitutio ad integrum* may result. The cells increase in vitality, the soft mass becomes organised, and, to be brief, goes through analogous changes to those observed in 'callus' in the repair of fracture, until the body

of the vertebra is again built up with true bone-tissue. But such a favourable course of things is very rare. It should be borne in mind, however, as the type of the healing process in this part which we are to aim at favouring by all known means.

Again, if the dyscrasia persist or increase, those parts of the mass most remote from active vascular supply undergo a change commonly spoken of as a loss of vitality, with consequent fatty degeneration, the result being the production of a caseous material at one spot or other. The mode of production of this material, however, is otherwise explained by competent pathologists, as we shall see presently. But, however formed, it may even now, under improved conditions of health, become absorbed to a great extent, the residue lying inert as a cheesy or cretaceous nodule in the midst of the recovered tissue. But with increase of ill health the process advances, the caseating change affects a larger and larger area, its products become more and more liquid, until eventually what is known as a cheesy abscess is the result—all this with little or no sensible disturbance of the temperature of the part.

Now if the process should have involved most or all of the body of a vertebra, the support to the spine anteriorly is consequently removed, and the bone above sinks down more or less upon the subjacent one. This movement is not of course sudden, but gradual, as the softening process advances, being most rapid if the patient have kept the upright position. While recumbent, the weight above having been taken off the affected spot, there may be little or no falling together. But when there is, rubbing and pressure of the diseased surfaces are produced, with consequent irritation, leading at last to hyperæmia, rise of temperature, and free formation of true pus. But, although the modes of origin of the caseous abscess and this latter fluid are primarily different, the two processes are usually associated in all but the very earliest disease. The subsequent behaviour of the resulting collections will be noticed lower down.

We turn now to the consideration of the *ætiology* of vertebral caries, a point upon which considerable difference of opinion still exists. The view hitherto commonly adopted in this country in regard to its causation may be briefly stated as follows: That it occurs only among particularly weakly children as a consequence of some violence to the column, whether by hyper-extension or flexion, by direct blow, or by a combination of any or all of these. Others, going a step further, describe this weakness as a distinct dyscrasia, characterised by low vitality of all the tissues, and a special liability to sluggish inflammation, a condition spoken of commonly, though vaguely, as the strumous or scrofulous diathesis. Here the violence, be it bruise or strain as the exciting cause is supposed to be followed by hyperæmia, gradually developing into a rarefying osteitis, with all its changes as described above. There is a great difficulty, however, in many cases in establishing the fact of any violence having occurred to the spine, and often where the disease is well marked it is beyond doubt distinctly negatived. This is one of the grounds upon which the theory of the origin of the disease in a specific poisonous irritant is favoured, a theory much more in vogue upon the Continent than in England. The exponents of this view (to state it briefly) regard scrofula as a definite septic disease, characterised by proneness to low inflammation of the growing tissues of the body, the result of irritants introduced into the body from without, and circulating in the blood. These irritants are nothing less, it is believed, than micrococci or microbes (to use the more general term of Pasteur) which have gained access to the body during some of those inflammatory conditions of the skin or mucous membrane so common in early life. These organisms, taken up by the lymph radicles in the first instance, are for the most part strained off, as it were, in the nearest lymphatic glands. It is by their aggregation and multiplication here that those cheesy masses so frequently found in glands, *e.g.* of the neck are supposed to be formed (Billroth). These caseous masses, then, are no longer regarded by pathologists holding this view as products of inflammation with secondary fatty degeneration, as first described by Virchow, but simply as colonies of microbes. They may, and usually do, eventually produce an inflammatory condition around them, but the material of which they are composed differs chemically and microscopically from the products of inflammation. Many of the microbes,

however, are supposed to escape the straining action of the glands, and thus gain admission to the general circulation. Arriving thus with the blood in the capillaries of the growing tissues, they not only interfere by blockage with the vitality of the latter, but act as direct irritants, producing either chronic congestion or (if aggregated in large numbers) actual so-called cheesy deposits. These may then induce inflammation around them, and themselves soften, leading to those ultimate results already mentioned. This aggregation of micrococci is held to be particularly favoured in bone by the arrangement of its vessels in wide lacunæ; hence the frequency of strumous disease of bone. It is further held that this scrofulous material may produce what is spoken of as true tubercle. Particles of the so-called cheesy deposits may be thrown off into the circulation, and be carried into some of the capillaries at a distance. Here they give rise to irritation and exudation of white corpuscles, which form around them soft miliary granulations, to which the name of 'tubercles' is given. This infection may either be a local one, the tubercles being formed close to the original focus of disease, or general, the characteristic deposit taking place at a distance, e.g. brain, lungs, or other organs. Koster¹ appears to have been the first to draw attention to the frequent presence of these small bodies among the granulations of proliferating synovitis; their existence in bone is more difficult to demonstrate.

This theory regarding scrofula and its relation to tubercle has, at all events, the merit of clearness, and explains, if true, many difficulties, which without it are constantly recurring to the mind. Whether it is true or not must be decided by further research; but, meanwhile, it is an attractive hypothesis with which most of our known clinical facts will be found to harmonise. One of these, the occurrence of caries in bone, without any injury to account for it, has been already alluded to. That this may take place there can be little doubt. I myself have none from facts which I have observed; one of which appears particularly worth mentioning here. I have found, namely, a patch of caseating caries the size of a sixpence under the dura mater of the anterior fossa of the skull, close to the tip of the lesser wing of the sphenoid. This was in the case of a boy who died at University College Hospital with the most extensive caries of the spine I have ever seen. Again in (fig. 84, p. 402) a focus of disease about the size of a pea will be seen quite isolated on the posterior surface of the body of a vertebra. It is difficult to imagine any injury specially affecting this spot alone, and not the rest of the corresponding body, especially in a very young child like this. Another point telling in the same direction is the well known frequency of general tuberculosis in those who have long had local deposits of strumous caseation.

For my own part, in studying disease of the spine, I have formed the conclusion that it is in some cases, especially among adults, doubtless of simple traumatic origin, without any particular diathesis to help, but that in others, notably children, there may be no injury to account for the condition, and that here we are driven to the theory of struma or tubercle. The conception of the latter as specific diseases in the sense just described, and of their mutual relations to one another, appears to me moreover most valuable from many points of view, even if it be no more at present than an hypothesis.

Turning now to the *secondary changes* produced in the spine by the local disease just considered, the very frequent, but for the future *not inevitable*, deformity must first be noticed. This is the well-known angular projection backwards of the spinous processes corresponding to the diseased bodies. The latter, softened by rarefying osteitis, as described in pp. 404, 405, fail to support those above them, which, under the weight of the trunk aided by the action of the abdominal muscles, consequently approach the next soundest bone below that affected. This, of course, produces a curve forward of the spine, with corresponding projection of the posterior processes. To this is sometimes added a slight lateral curve (but only in the lower dorsal and lumbar region) if the disease have involved one side of the bone more than another; this may even be marked if one of the articular processes be implicated, but it is rare.

¹ Hueter, *Gelenkkrankheiten*, 2nd edit. 1870, p. 134.

But this is not all. The abrupt curve in the column now existing would bring that part of the trunk above it quite out of the perpendicular, and the centre of gravity of the body would lie much in front of its base of support, if no compensation in balance took place; moreover, the face would look downwards instead of forwards. To obviate both these faults, the patient involuntarily produces what is known as the 'compensatory curve' in those parts of the spine which are still unaffected. Thus, if the angular curvature be produced in the lower dorsal region, the patient involuntarily increases the normal lumbar curve, and so throws the upper part of the trunk backwards, and thus more over the base of support. At the same time the cervical curve is increased, and the concavity forwards of the upper dorsal region obliterated, if not converted into a concavity backwards, continuous with that of the neck. The head and shoulders are also thus brought into the perpendicular. Fig. 86

FIG. 86.

FIG. 87.

The figure copied from a photograph, shows the appearance commonly presented in a case of angular deformity from spinal disease. The patient, a delicate girl, fourteen years of age, had become deformed to the extent seen in the drawing, shortly before her admission into the hospital. She had been generally able to go about and attend school during the progress of the deformity. Lately she failed in her power of walking. But it was ascertained by frequent observation that this defect did not proceed from paraplegia, but only from inability to balance herself in the newly deformed condition of the upper region of her body. She became strong on her limbs, after a short stay in the hospital.

is intended to represent this whole process diagrammatically, from the production of the angle to the establishment of the erect position of the deformed body. It must be remembered, however, that the process of deformation and that of compensation go on *pari passu*, and not at different times; also that the position of the compensatory curve differs with the situation of the disease. In fig. 87 it is seen in the lower dorsal region, the angular deformity being seated above.

Our great aim, however, in the future must be to recognise the affection before any deformity has been produced. For it must be remembered, too, that *osteo-myelitis granulosa* may be present to a considerable extent, and yet no angular curvature exist. Thus we may find, after death, the front of one or more vertebral bodies eroded, pitted, and covered with soft granulation-tissue (fig. 85), or perhaps an extensive collection of pus, and yet the continuity of the column in no way affected.

Such cases must be borne in mind as explaining possible spinal abscesses where

no deformity exists. But between them and others where one or more bodies are completely destroyed (fig. 88) there is every possible gradation until, in place of erosion of the front of several bones, as described, we may find total destruction of perhaps six or eight vertebral bodies, and a consequent bend in the spine to the extent even of a right angle.

Now it may be taken as generally true that, wherever there is much deformity, there is sure to be an abscess somewhere, large or small. Whatever be the nature of the initial lesion, the destruction of tissue, increased mobility, and consequent irritation are almost certain to lead to the formation of pus. But it does not follow that this abscess shall point externally at once. It may not do so for a long time, or

Fig. 88.

The patient from whom the specimen represented in the figure was removed was a blacksmith, twenty eight years of age, and was admitted into the hospital for a *psoas* abscess, about the size of a large orange, situated in the left groin. He had an abrupt angular deformity in the back, with protuberance of the sternum; and his muscles, particularly those of the upper extremities, were largely developed. The deformity had taken place when he was fourteen years of age; and it had not increased since. His father being a blacksmith, he had been early put to the same work, and had continued uninterruptedly at it all three weeks before his admission, when he first noticed the swelling in the groin. On the abscess being tapped, a straw-coloured fluid was discharged; the opening did not heal; ordinary pus continued to flow; and he died exhausted with hectic fever. It will be remarked in the figure, that the posterior arches and articular processes of the vertebrae, at the seat of disease, have been firmly united together by bone. It may also be noticed that an intervertebral disk has been left untouched, while the bones above and below it are extensively destroyed.

as a consequence the column falls forwards, the lumen of the tube is, if anything, larger than normal at the affected spot. Again, the shortening of the canal tends to relax the cord, and thus admits of its accommodating itself the more easily to its altered conditions. It is a remarkable fact, too, that, although one or more of the bodies may be totally destroyed, injury to the cord from actual dislocation is very rare. This is perhaps best explained by the gradual welding together of the parts by plastic matter effused around the carious spot, which usually takes place. Again, all care is taken by the patient himself to shield the part from every movement or violence,

even not at all, being absorbable under a return of the part to favourable conditions for healing. Again, it may reform long after the part has consolidated, if the patient get into bad health, or meet with any slight overstrain of the diseased part. A knowledge of these points is necessary for proper treatment in different cases. The direction in which these abscesses enlarge and eventually point will of course depend upon the position of the carious focus, and will therefore be considered later on in relation to cervical, dorsal, and lumbar caries.

The state of the spinal cord during the changes we have been considering now claims attention. As a matter of experience, its functions are ultimately but little interfered with in the majority of cases of the kind. As far as the mere shape of the column is concerned, this is only what we might expect when we come to examine into the mechanism of the change. When the canal is bent upon itself, in a case of caries, it is not a question of an abrupt 'buckling,' at one spot, such as is produced when a piece of tin tubing is forcibly bent. In such a case the 'buckling in' of the anterior wall towards the posterior would inevitably compress the cord. But here there is a loss of substance in the anterior wall of the canal, and when,

and this being so, the other articulating portions of the bone are adequate to the lessened call made upon the strength of the part. Nerve symptoms are, however, observed from time to time with vertebral caries, and due to a variety of causes. They may be produced, it must be remembered, as well by altered conditions around and about the nerve-trunks leaving the cord as by damage to the latter itself. Thus many affections between complete paraplegia and slight loss of power or numbness in part of a limb are met with. The factors in the production of these nerve affections will probably be one or other of the following :—(1) The soft *débris* of advanced osteo-myelitis granulosa may be squeezed backwards against the posterior common ligament now relaxed (fig. 84, p. 402), and press it against the cord as the spine falls forwards, and the sound bone above closes down upon the diseased mass. (2) The same kind of pressure may similarly be exerted upon the nerve trunks as they pass through the intervertebral foramina, or after, and without affecting the cord. (3) The proximity of the focus of disease to either the cord or nerves may produce sufficient congestion or inflammatory effusion of serum about them to interfere with their functions by simple pressure. (4) In the same way, actual inflammation of these nervous structures may be produced, and go through any or all its stages, even to complete disorganisation, which is, however, rare. (5) Finally, an incautious movement of the spine may rupture an engorged vessel in the congested part, producing extravasation of blood and immediate compression of the nervous structures.

The diagnosis of these causes of nerve symptoms, one from the other, is often attended with considerable difficulty, but must nevertheless be studied, as upon its correctness depends, in many cases, the suitability of our treatment of the carious spine. Only the more general grounds for diagnosis will be alluded to here, however.

The *first* cause mentioned is, perhaps, not difficult to recognise. The symptoms are possibly only present if the patient is in the erect position, or are worse at such times. There is probably no pain in the limbs. If the diseased part be relieved of the weight of the body above it by lifting the latter, the pressure on the soft *débris* is removed at once, and the nervous symptoms disappear. This I have seen in patients with marked deformity, and inability to support themselves on their legs, when it has been necessary to partially suspend them for the application of a plaster corset. During, and after this, they have been quite relieved, and the relief has been complete, as long as the spine has been supported.

The *second* cause is diagnosed upon the same grounds, and by the limitation of the defective power to one or more nerves. These troubles are often met with in the arms with cervical caries.

The *third* cause is not easy of positive diagnosis. But here the symptoms will probably have set in rapidly after some exposure either to chill, exposure, or slight injury, in one who, though affected for some time with angular deformity, has up to that time shown no symptoms. There will be no sudden increase of the deformity or of pain on pressure, no pain or twitching in the parts whose nerve supply is affected; probably no rise of temperature.

With the *fourth* cause the symptoms are generally marked, the most important being as follows: pain at the diseased region of the spine, increased by movement or jarring of the part, and radiating along the course of the nerves given off here; hyperæsthesia at the peripheral distribution of the latter; twitchings of the muscles are also complained of before loss of their power in marked cases. The temperature of the body rises usually, and sometimes to an extreme degree.

The *fifth* cause is difficult to recognise in many cases, but may be tolerably apparent in others. The evidence is negative; no increase of pain, tenderness, or deformity of the spine is noticed. The loss of motion or sensation comes on rapidly, and without being preceded by muscular twitchings, pain along the nerves, or hyperæsthesia. The temperature is not affected.

As to the varieties of nerve conditions produced in the ways just alluded to, they have nothing further about them of special interest to the surgeon, and the detailed description of the ultimate changes induced through them in the cord, and their treatment in detail, must be left to the medical works devoted to this particular subject.

Having now considered the ætiology and general course of caries of the spine, there remain for study the *diagnosis*, *treatment*, and *prognosis* of it in the several regions of the column, in each of which it presents peculiarities. A few words, first, as to the *general* indications for treatment of the disease, will save reiteration when dealing with the three divisions separately.

Our success in the *treatment* of any case of spinal caries will be in proportion as we secure early local rest for the spot affected, and improve the general nutrition and vitality of the whole body. The mode of meeting the first of these requirements for each region of the spine will be dealt with in considering that particular part; the way of encouraging the latter now requires brief notice. Whether strumous disease originate in injury or the presence of microbia in the tissues, these bases of our treatment are equally sound. If the latter theory be correct, there is a constant struggle, so to speak, between these lower organisms and the cells of the human tissues. These, in a state of normal activity, are capable of resisting and overcoming their adversaries, but when their own vital force is lowered the reverse is the case.

It must be remembered, firstly, that in securing immunity from pain the nutrition of the body is indirectly improved. Pain means 'nerve wear and tear,' and this means loss of vital force affecting all the tissues; it means loss of sleep and appetite, and assimilative power. And it is remarkable how soon both the desire for food and the capability of assimilating it increase when, by simple mechanical support, the pain accompanying spinal caries is relieved. The same relief may be obtained by confining the patient to the recumbent position, and so relieving the column of all weight. And, in certain cases, especially with very young children, no doubt such treatment is the best we can employ. But, as a rule, the debility so induced by prolonged confinement militates strongly against repair, even though the disease cease to advance. Another evil, due to the horizontal position, is that passive congestion of the structures involved in the disease is favoured, unless the patient lie in the prone position. Moreover, if there be any pus present, it remains in contact with the diseased focus, or slowly sinks through the back muscles, instead of gravitating away from the carious spot, as is the case where the patient is enabled to preserve the erect position, and a psoas abscess forms. This natural drainage of the affected spot is of much importance. But, besides attention to these considerations, much remains to be done. Fresh air, light, suitable and sufficient food and clothing are called for. One of the great advantages of the various spinal supports is that it brings the first two of these items within the reach of almost all. The plaster-of-Paris corset enables the patient to take quiet out-door exercise on bright days, and often to escape ill-ventilated and overcrowded rooms in the case of the poorer classes. But it is a melancholy fact that we, whose hospital patients come from the poorer classes of the metropolis, are too often powerless to treat the disease, owing to the lack of the two other common necessities of life, suitable and sufficient food and clothing, if the patient be treated, as ought to be the case, outside the hospital. What is wanted is increased accommodation in country 'Homes for the sick,' preferably at the seaside, where our cases might be left for months, and still receive skilled surgical care. The ideal home for such cases would be in a pure, dry atmosphere, bright, but sheltered, so as to admit of out-door exercise at all times of the year. There should be a full supply of light, nutritious food, into which fresh, well-cooked meat enters freely. Saccharine matters and the heavier fats would be avoided, as straining the digestive powers too much. On the other hand, certain of the lighter fats, especially if half-digested, or pancreatised, should be supplied abundantly, in the form of milk, fresh butter, and cod-liver oil.

As to the drugs which have been used internally in the constitutional treatment of struma or tuberculosis, they are numerous. Those most in use amongst surgeons are the various preparations of iron, phosphates of lime, iron, &c., but, above all, iodine, in several combinations. How this latter exerts such a beneficial influence over diseases of the strumous class is not established. Those who believe in the germ theory of scrofula, as given above, see an easy explanation of the fact in its known power as a germicide. Some of those who hold this view, report favourably also upon the local hypodermic injection of solutions of carbolic acid, in early cases.

into or around the diseased spot, on the same grounds. This treatment, as described by Prof. Hueter (*op. cit.* Th. iii. p. 85), one of its strongest advocates, is carried out for spinal disease as follows:—'The point of an hypodermic injection-needle is passed through the thick muscles of the back, at a point between the transverse and spinous processes until the posterior periosteal surface of the lamina is reached.' Then one gramme of 3 per cent. solution of carbolic acid is slowly injected into the tissues around the bone. This is repeated every day for a considerable period. This surgeon regards the effects of his treatment as undoubted even where, as is the case here, the diseased bone is not actually reached with the needle; this is made up for, he believes, by the diffusibility which carbolic acid is known to possess. The effects, however, where the needle can actually be thrust into the bone, as in disease of the end of the femur, are said to be more marked. What place this measure is eventually to take in surgical practice only long and extended experience in the future can determine.

As to the use of local antiphlogistics, such as are employed in the inflammatory bone affections elsewhere, they are not in favour at the present day in the treatment of myelitis granulosa of the vertebrae. Applications of ice, setons, blisters, and other counter-irritants have fallen almost completely into disuse. This is perhaps to be regretted in the case of some of the latter, where the treatment of very recent osteitis is in question. If recognised very early, we have as good reason to expect benefit here as elsewhere from free and repeated blistering, or the use of the actual cautery at either side of the spine, provided always the sore spots left do not interfere with apparatus for the immobilisation of the column. Later on in the disease this treatment could only be hurtful.

We have now to consider the peculiarities of strumous caries in the different regions of the spine.

CERVICAL REGION.

In the *cervical* portion it commences almost always in early life, though it may persist into adult age.¹ Here there is usually no history of injury, the affection starting without any assigned cause, and progressing slowly. The first sign of the disease noticed in the child will be a stiff cautious gait, the head being fixed and carried with the rest of the body, as the patient desires to look right or left. This is simply an involuntary act on the part of the patient, in order to protect the inflamed part from movement, and has no relation with the fixation, which takes place later from consolidation of plastic exudation around the focus of disease. At this time but little pain may be complained of, so long as the head is steady, but any attempt to active or passive motion of the part will produce much suffering. Here, however, the bodies of the vertebrae being so small, it is not long before they yield to the softening process, and the head bends slowly forwards; the chin approaches the root of the neck, and one or more of the spinous processes becomes prominent. The latter rarely form so sharp an angle here as elsewhere, owing to the fact that several vertebrae are usually involved in this case. What has been described as compensation is now noticed. This curve, produced involuntarily in the healthy part of the spine, to make up for the change of shape in the diseased part, is, in this case, situated in the dorsal region, whose normal concavity forwards may be obliterated, or even converted into a convexity to make up for the exaggerated curve forwards, now present in the cervical region. But for this compensation the chin would rest upon the neck, and the face look downwards. With it the patient can look fairly straight before him. A patient with marked angular curvature in the neck presents a most remarkable appearance, when stripped. Above, the head is seen hyper-extended, then comes the deformity, and from it downwards one long curve forwards of the whole column, involving both dorsal and lumbar regions. In the former the spines are seen sunk in between the shoulder-blades, which are abnormally prominent.

The next consequence of cervical caries noticed will probably be the formation of swelling of greater or less extent over the seat of disease. It may be trifling for a

¹ Some anomalous cases of late origin of the disease are referred to on pp. 421*et seq.*

long time, giving little more than a sensation of increased resistance to the finger on palpation, or may rapidly increase and become doughy and brawny. Sometimes abscess is the first indication of mischief here, but rarely and only when the osteo-myelitis granulosa is limited to the anterior or lateral surfaces of the bodies. In such a case it will form a soft fluctuating or doughy swelling on the posterior wall of the pharynx, which may be reached with the finger. This may, however, increase to a size sufficient to produce dysphagia, or even dyspnoea, before attention is drawn to it. But, as a rule, abscesses in connection with cervical caries point in some part of the neck, at a distance often considerably below the seat of origin. The most usual position is in the posterior triangle of the neck, in front of the trapezius, or low down close to the outer border of the cleido-mastoid muscle. The reason for this is not far to seek, if we remember the direction of the planes of the cervical fascia, and its sheaths for the muscles running downwards and outwards from the neighbourhood of the focus of disease. Rarely, the pus passes directly backwards from the latter, and points at either side of the ligamentum nuchæ. A doughy swelling precedes its actual appearance for some time, and requires care in diagnosis. Occasionally, it happens that the pus does not point in the neck at all, but makes its way into the posterior mediastinum, sinking, perhaps, as far as the diaphragm. Here it may burst into the pleura or pericardium, or, running sideways or forwards, open externally under the border of the ribs. Again, it may run down outside the thorax, but under the clavicle, and burst externally. The chief immediate dangers of abscess from cervical caries are that it may rapidly induce dyspnoea, from swelling in the pharynx, or that it may burst here, producing suffocation from entry of the pus into the air-passages. And, even if this immediate peril be escaped, the patient may succumb later to broncho-pneumonia, induced by the entrance of pus into the lung. Apart from these, the remote dangers are less imminent when such an abscess opens within the pharynx than when it bursts on the surface of the body. The probability of septic changes in the latter case are much greater. For the general treatment of such abscesses, see p. 417.

The *diagnosis* of cervical caries is not difficult in its later stages; but it is so early in the disease, and here mistakes occasionally arise. And yet, if we are to be of real service to this class of patient, we must recognise their disease very early. The pain here causing restrained movement of the neck is apt sometimes to be taken for rheumatism, so often present in this part. It may be distinguished from the latter, however, by the fact that it is constant and gnawing, worse at night, is aggravated by movements or by pressure upon the top of the head, and relieved by lifting the latter upwards, while rheumatic pains are worse in the morning, are 'catching' in character, are relieved by moving the part about for a little, and by friction. With caries there will be deep-seated tenderness, too, on pressure, and probably some swelling and local rise of temperature. Close observation of the movements of the head, which produce suffering, may also help. Thus passive flexion will be more painful in the case of caries than with rheumatism. When an abscess has once formed, or deformity or nerve symptoms have appeared, there can be but little difficulty in diagnosis. The latter vary from slight aches or loss of power in the course of some of the cervical or brachial plexus of nerves to complete paraplegia. When the head is gently lifted and well supported, these symptoms disappear when observed early, often on the moment, and there are few more interesting or remarkable sights in our experience than to see this take place.

The *treatment* of cervical spine disease taxes all our powers. Apart from the general and local measures described already (see p. 410 *et seq.*), the only hope for the patient lies in complete rest of the part by immobilisation. But this is extremely difficult to secure, owing to the natural mobility of the neck, with, in addition, probable destruction of one or more of the bodies of the column. Here, then, is an extra reason for recognising the disease at its outset, and exerting ourselves to the utmost in its treatment. Of the many means which have been employed in the latter, only a few need be mentioned. Confinement to the couch is undesirable, for reasons already given (p. 410), and except in the case of very young children, for whom mechanical appliances are less suitable, should not be persisted in. Those appliances, then, which, by fixing the head and relieving the diseased spot of its weight, enable the

patient to obtain exercise in the vertical position, and fresh air, are designed on the soundest principles of treatment. We have here three more or less stable parts to work upon—the head, the shoulders, and the pelvis—and these are variously utilised for immobilising the cervical spine. Some of the earlier contrivances consisted simply of a high collar or stock of leather, gutta-percha, or pasteboard, resting below upon the broad part of the neck, and receiving upon its upper padded border the whole weight of the head, through the jaw and occiput. The latter is thus kept from flexion and extension to a considerable extent. This appliance, however, has manifest disadvantages, and is not in very much favour at present, though some still employ it. Professor Hueter speaking highly of it. It is, at all events, simple and cheap. But those appliances which take their base or support from the pelvis are generally regarded as the best. Of these, two typical examples only need be mentioned here.¹ One was designed many years ago by Dr. F. Taylor, of New York. It consists of a broad, well-padded pelvic-girdle made of iron, from which two steel bands ascend one on either side of the spinous processes as high as the occiput; here they terminate in a kind of crutch, which supports the latter and the chin, to which it can be adjusted by the action of screw-joints. These vertical rods are kept in position between the shoulders by straps which pass over and under the latter, and are prevented from galling any points of pressure by careful padding. This is an excellent contrivance, and has done good service in its time. In Professor Sayre's Plaster of Paris Corset and Jury-mast, however, we have a much better appliance, in so far as it provides a better support for the head, and, while preventing flexion, allows at the same time more freedom, as far as rotation of the latter is concerned. This movement takes place, of course, at the upper joints of the spine, and can be free without disturbing the disease below, unless these upper articulations themselves are affected, which is rare. Personally, I have no hesitation in giving the preference to this contrivance over all others, and this in spite of several disadvantages, to which all who have had large experience of its use must be fully alive. Some of these may be mentioned. In the first place, great care and considerable skill are required in the application of the corset; for, without this, it is not only most irksome in locomotion, but may cause serious embarrassment to both respiration and digestion, quite apart from the minor troubles of galling, even to ulceration. It requires to be reapplied every six or eight weeks to avoid the same evils, especially with growing children. Among the poorer classes, it often becomes infested with vermin, or otherwise very unclean. During its use, the hygiene of the bath must be foregone. When worn for a very long time, I think I have noticed that the patient contracts a habit of breathing almost exclusively by the diaphragm, owing to the close fit of the corset, and even when this is not tight, simply for the reason that it involves less exertion than that of lifting the thorax inside this firm carapace with each inspiration. The consequence is an apparent wasting of the thoracic muscles, and arrest of development of the whole chest. Many of these disadvantages, however, may be overcome, and of the remainder it may be said that they are more than counterbalanced by the comfort and rest to the diseased part given when the corset is well applied, and by its lightness and cheapness bringing it within the reach of the poorest. Ill applied, however, I have seen it most harmful.

DORSAL REGION.

Turning now to disease in the *dorsal* region of the spine, we find it essentially the same as when occurring higher up, but modified here by the existence of more medullary tissue in the larger vertebral bodies, and by the greater weight to be supported by the column. As regards causation, a history of injury is perhaps more frequently forthcoming than in the case of cervical disease.

Here, too, a diagnosis is easy when the disease is advanced, but by no means so in its earlier stages. The first sign will probably be a cautious gait and dislike to exertion, the patient evincing a desire to lie down whenever possible; at this time

¹ For a more detailed account of them, and of those other contrivances used in the treatment of the various forms of spinal diseases, the reader is referred to Dr. Little's article on ORTHOPÆDIC SURGERY.

there may be a slight, but constant, pain at one part of the column, especially at night, aggravated by rotation or jar to the spine, or on tapping the part with the fingers, but as yet no deformity. Later on, with increased dislike to exertion, the patient will be observed involuntarily to grasp any surrounding objects which might afford support for the upper part of the body, and a little later to rest the hands upon his own thighs with the same object. The respiratory movements of the thorax will now probably become more or less restricted, in order to reduce the play of the ribs against the affected spine as far as possible, and to avoid extension of the latter during inspiration; the breathing will consequently be chiefly diaphragmatic. Other evidence of this disease, when seated in the lower dorsal and lumbar vertebræ, is frequently present in flexion of one or other thigh. This is due to the involuntary contraction of the psoas muscle, whose insertion is involved in the inflammation. This is easy to understand in the case of the lumbar and last dorsal spine, but even with disease of the bones immediately above the latter the same phenomenon may often be noticed, probably because some of the products of inflammation have made their way downwards as far as the insertion of the muscle, but without as yet forming any distinct abscess. The patient, in such a case, will stand with one thigh advanced beyond the other, and the pelvis drooped correspondingly on the same side; there will be slight scoliosis and the body will be bent a little forwards. If told to stand 'at attention' erect, and with the heels well together, he can do so, but will very soon reassume the old position, if left to himself. This irritation of the psoas is often seen very early before any angular curvature exists, and is therefore valuable evidence. It is the first stage of actual psoitis, which is present in almost every case of marked curies of the vertebræ lower down. With psoitis proper the symptoms will be the same as those just given, but more marked; there will be greater flexion of the thigh, and the latter will be more fixed; neither the patient nor surgeon is able to straighten it without much pain being produced, and attempts to bring down the limb only result in the production of marked lordosis, the pelvis rotating downwards and forwards on its transverse axis, and the lumbar spine following it as the thigh comes down straight (see DISEASES OF JOINTS, fig. 77). The position of the thigh in both cases is almost identical with that assumed by the limb in early hip-joint disease, and hence mistakes sometimes arise, unless a very careful examination of both joint and spine be made. Eventually the appearance of angular curvature will, in most cases, clear up the diagnosis. But it should never be forgotten that very marked disease of the vertebræ may exist for a long time without the production of this deformity (see p. 404), and that we must concentrate our attention upon such cases long before it does appear. The curvature itself is not to be treated in the sense of removing it. Attempts to improve it, either by suspension or other extension, are now generally discountenanced.

Abscess in connection with dorsal curies nearly always takes the same course. We find it starting at the front or sides of the vertebræ, and running downwards until it reaches the psoas muscle, on one or both sides,¹ the direction of which it follows in a way to be described in dealing with lumbar curies. Less frequently it passes backwards between or external to the transverse processes, and opens on the back. But this is only found in cases which have been confined for a long time to the recumbent position, and where the disease is extensive. Another ill effect of confinement to the couch is seen occasionally when the focus of disease is in the lower dorsal region. As the patient lies, the softening spot may be on a higher level than the middle of the dorsal curve. The consequence will then be, as I have seen in more than one case, that the pus, instead of following the course of the psoas downwards away from the spine, and in a direction the least hurtful of any, gravitates towards that part of it usually above, but now the deepest of the dorsal curve, where it lies bathing the bone in a most harmful way, until possibly it makes a passage through the dorsal muscles or spreads under the pleura.² Such cases would

¹ Large psoas abscesses on both sides are not common; when they do occur they are generally very unequal as to size. The author, however, has had to treat a case in which a large psoas abscess presented on both sides below Poupart's ligament, showing no difference in size or date of appearance.

² In this way I have seen fatal pleurisy produced in more than one case. (See *Trans. Path. Soc.* 1878, p. 191.)

probably have rapidly developed psoas abscesses if placed in the upright position in a corset, and so the diseased part would have been naturally drained. In those cases in which I have seen pus make its way into the pleura, a very considerable attempt had already been made by nature to limit its effusion by the previous production of adhesion all round the thinning spot, but this had been inadequate.¹ The treatment of these abscesses will be considered later in dealing with the question generally.

Another ill effect of extreme dorsal caries may now be briefly considered to which attention has been called of late years by several observers, especially by Dr. Hilton Fagge (see 'Guy's Hosp. Reports,' 1872; also a communication by the author, 'Path. Soc. Trans.' 1880). This is the alteration in the direction and shape of the aorta, produced when a sharp angle is formed in the spine by carious destruction. The vessel is so closely tied in to the column by the intercostal arteries, that it is compelled to follow all the changes of shape of the latter. Hence when abrupt kyphosis exists, the aorta is sometimes acutely flexed upon itself and an actual 'buckling in' of its anterior wall takes place, such as is produced in any elastic tube, when bent sharply. Here, too, the same effect may be noticed in the lumen of the tube—namely, alteration in shape and obstruction. On vertical section of the vessel, the anterior wall appears to form a kind of spur reaching across the diameter of the tube nearly to its posterior wall, or the whole vessel may be, so to speak, wrinkled into coarse folds. The result of this change is believed to be in many cases cardiac hypertrophy, with all its consecutive evils. In one or two cases of angular curvature, I have observed this hypertrophy, but whether as a consequence of change in the shape of the aorta, there was no opportunity of ascertaining, the patients having lived. In another of my cases ('Path. Trans.' vol. xxxii.) the change in the aorta was well seen, but here there was no cardiac hypertrophy. This may have been due to the fact that the case was not of very long standing, the patient being a child. The point is well worth further study in a larger number of cases.

The effect of the change of shape of the spine upon the form of the thorax and abdomen generally finds expression in the hindrance to the functions of the organs contained in these two cavities. For, although the latter do accommodate themselves to their altered relations by degrees, nevertheless, under the altered conditions as to space and pressure, as the thorax falls down upon the abdomen, their vascular supply is always more or less deranged, leading to venous engorgement, &c. Hence patients with marked angular deformity in the lower dorsal region are not only cramped as to the play of inspiration, which is of that short 'grunting' kind so characteristic of the affection, but are also observed often to suffer from various digestive troubles, referable to passive engorgements of the abdominal organs.

The *constitutional* and *local* treatment of the bone-lesion in dorsal disease is based upon principles already considered (p. 410 *et seq.*), and which need no further consideration: a few words only remain regarding suitable apparatuses for mechanical treatment. What is required of any such is that it shall transmit the weight of the upper limbs, head, and thorax directly to the pelvis, without the interposition of the affected spine, and at the same time immobilise the latter. Of the numerous means designed to this end, decided preference is to be given to Prof. Sayre's plaster-of-Paris corset. But, after large experience of its use and post-mortem examination of cases treated by it, which have died from one or other cause, I cannot but think that any endeavour to *correct* the deformity by suspension and application of the jacket is improper practice. What should be aimed at is simply to extend the spine until the weight of parts above is removed from the diseased spot, and any possible spasm of muscles adjacent to the latter is counteracted (as Prof. Sayre believes), and to fix the column thus for long periods. If more than this is done, evil results may follow, and I believe, from post-mortem observation, have followed. It is not that the column at the diseased spot is liable to be torn or loosened by suspension, with damage to the cord or its meninges, or even to the bone-tissue itself. This is prevented by the

¹ Cases, however, are recorded in which adhesion has taken place between the two layers of pleura of sufficient strength to limit the extension of the abscess, so that the latter has made its way into the lungs, and been coughed up, the patient recovering. See Shaw 2nd ed.

support of the powerful abdominal and dorsal muscles attached to parts above and below the softened spot, which would always take upon themselves any strain not already borne by the transverse and other ligaments still unaffected, or even to the exclusion of the latter from any tension. The dangers which seem most likely to arise from over-suspension are disturbance of the products of the carious process, and consequent increase of irritation, local and general; also stretching of the walls of the small caseous abscesses, so often present in front of the softened bone, this stretching leading possibly even to rupture at one spot or another, with pleuritis or other secondary dangers. I believe I have seen this in a case upon which it fell to my lot afterwards to make a post-mortem examination. As compared with Sayre's corset jacket, the poicoplastin appears a very second-rate appliance, and little more than a makeshift. Its use has more than anything originated, perhaps, in the desire to avoid the trouble and loss of time incidental to the application of the plaster-of-Paris corset by the surgeon himself. Taylor's apparatus, too, although undoubtedly useful, in so far as it prevents the spine from falling forward, comes short as compared with the rigid, well-moulded tube of plaster of Paris, in not fully taking the weight off the diseased bones, and in not preventing rotation at the carious focus, as the latter does in a great measure. None of the other numerous older appliances need be considered here; Sayre's corset and some of its modifications have justly superseded them. Personally I regard these modifications as unnecessary as a rule, the original form, if accurately fitted and kept clean, answering all the requirements I am aware of. The use of two underverts, one of which may be removed when worn or soiled, without cutting up the corset, and leaving the other behind, is a suggestion which may be found of value when dealing with very careless or dirty patients.

LUMBAR REGION.

In considering *lumbar* caries, but little has to be added to what we have already studied in cervical and dorsal disease. The conditions are, however, here particularly favourable to the occurrence of myelitis granulosa, the medullary tissue being abundant, and the weight and strain thrown upon each of the vertebræ very great.

Early *diagnosis* is as difficult here as elsewhere, and equally important. The first evidence of the disease noticed will probably be inability to retain long in the upright position, or great fatigue in walking, with a sensation of weight in the limbs, the patient showing great listlessness, dislike to exertion, and a desire to lie down. Some pain and tenderness will probably be felt soon after, on pressure over one or more of the vertebræ behind, and in front through the abdominal walls, and a little later pain on rotating the spine. This is usually most noticed when the patient turns over in bed. The next thing observed now will in many cases be irritation of the psoas muscle, with flexion of one or both thighs, as already described (p. 414). The characteristic gait will then be assumed, the body being bent forwards, and the hands resting upon the thighs, or involuntarily seeking support from surrounding objects. A little later the prominence of one or more spinous processes, with great suffering on movement, will leave no doubt as to the diagnosis.

It is now that *abscess* may be looked for, and it may sometimes be easily recognised, even while still small, by careful *palpation*. If left untouched, it will present itself in one of the following positions—the region of the psoas muscle, the groin, the loin, or perinæum; it may even pass out of the sciatic notch, and point in the trochanteric region, or fill the hollow of the sacrum, and press upon or burst into the rectum. In some rare cases it spreads in all these directions at once, as shown in a preparation in University College Museum, No. 444. When the pus passes backwards into the loin, it is usually under the force of gravity, owing to the patient having been kept in the recumbent position from the first, also owing to the fact that the pus travels along in the direction of least resistance, i.e. along the sheath of the psoas. In other cases it spreads outwards over the front of the quadratus lumborum, and passing over the crest of the ilium, forms a large collection on its dorsum. But in by far the largest proportion of cases the products of lumbar caries sink in the direction of the psoas muscle, where patients have kept their feet for any considerable time

after they commence to form; this is also true of the lower dorsal region. Arrived within the psoas sheath, the pus may form there a very large collection, or rapidly sink farther, reaching the thigh under Poupart's ligament or more rarely pointing above the latter; in extreme cases it may even travel as far as the knee or ankle. Sometimes, but rarely, the pus finds its way from the psoas sheath into the inguinal canal, where it may simulate hernia.¹ Instances again are met in which, in travelling downwards, the pus does not follow the psoas far, but sinking over the brim of the true pelvis, forms a collection in the hollow of the sacrum, which may eventually burst into the small intestine, rectum, or bladder (see Shaw, *loc. cit.*) or through the perineum. Again, on entering the pelvis the fluid, in other cases, will turn outwards through the sciatic notch, and running along the small rotator muscles, point in the neighbourhood of the trochanter. Here, if the collection be small, difficulties in diagnosis may arise, and it may be mistaken for a suppurating bursa over the trochanter. One particularly interesting case of this nature occurred in the author's practice. A man rapidly developed dorsal caries, and shortly afterwards became paraplegic. At the end of three months spent in bed an abscess formed behind the right trochanter and burst, discharging a large quantity of pus and some fragments of bone. Soon after this the paraplegia disappeared, and when I last saw him he was walking about the picture of health but for the angular curvature.

The special management of these and the other spinal abscesses is considered below.

The treatment of the bone-lesion in lumbar caries requires no particular description now (see pp. 410, 411). It need only be remarked that, if the conditions here are very favourable to the occurrence of osteo-myelitis granulosa, for reasons given pp. 401 and 403, the disease is yet easier to treat mechanically in the lumbar region than higher up. Whatever appliance is used, there is more surface above the seat of disease to be grasped by it than in the dorsal or cervical affections, and consequently the inflamed part can be better fixed. A patient with a carefully-fitted plaster corset is well able to walk about and enjoy exercise in many cases, and far more so than where the disease is dorsal, though the corset be equally well applied, and the superincumbent weight upon the affected bone be far less. Another point may be noticed—namely, that it is not necessary to carry the plaster jacket quite so high here as for dorsal disease. Provided it be accurately and firmly planted upon the pelvis, it need not rise quite to the axilla. Again, it should be remembered that, in the opinion of many surgeons, of whom I confess myself one, this corset is unsuitable for infants and very young children. With them the pelvis is as yet so slightly developed, that there is no marked bony outline to be grasped by the lower border of the appliance, whereby the upper part of the body could be steadied, while the latter itself can change shape in many directions, owing to the great mobility of the infant spine. The pelvis consequently slips about inside such a carapace easily, and its only hold is upon the thorax, and that but an imperfect one. There are other reasons too why it is less applicable here than at a later age, such as the difficulty of keeping it dry, the liability there is of chafing the delicate skin of infancy, and the embarrassment, however slight, to the movements of respiration, which would be much more serious at this age than later, for obvious reasons. These conclusions are borne out by personal experience, after a wide use of the corset. I am aware that they are not in harmony with the views of some surgeons fully competent to speak on the point. But I can only say that they have led me to abandon the use of this appliance, for very young children, for some time past.

We turn now to the consideration of the treatment of abscesses in connection with caries of the vertebrae.

A few main principles guide us in dealing with these, whether they are due to cervical, dorsal, or lumbar caries. First, they need complete rest, as long as they are small, slow-growing, and beyond reach. Second, if they are steadily increasing

¹ Brodie, *loc. cit.*; Shaw, *System of Surgery*, 2nd ed.

and approaching the surface, they call for evacuation of all their fluid and solid contents, if necessary, with the sharp spoon, if the latter be abundant, as it often the case. Third, efficient drainage of all after products is to be maintained. Fourth, the strictest antiseptic precautions must be observed from beginning to end, i.e. from the opening of the collection to the definitive cicatrisation of the drainage opening.

That such abscesses may become absorbed under rest to the spine, and improved general hygiene, we are taught by abundant direct evidence, as well as by analogy. The following is a good illustration of what may take place in this direction. During 1880 I treated a child for lumbar caries. She had been coming backwards and forwards to hospital for some years, at long intervals, and for the last year tolerably regularly, for the application of the plaster corset. No positive diagnosis of psoas abscess had been made, though there was psoitis and marked curvature. The child at last appeared almost cured, as far as the spine was concerned, and had been walking about for a long time, and going to school, when she became suddenly ill, and developed symptoms of tubercular meningitis, of which she died in a few days. A post-mortem examination revealed the fact that a very considerable abscess had, at one time or another, occupied the position of the left psoas muscle. This I now found reduced to a mass of dry, tough, cheesy material, with calcareous plates scattered through it. It was about the size of an adult thumb, and lay as described, running off above as a narrow tract to the focus of disease, and below in another tube narrowing under Poupart's ligament, to swell again into a second small collection of similar material, about the size of the last joint of the thumb. There was hardly a trace of pus anywhere, and yet this dry cheesy mass must have represented a very considerable abscess, which had escaped notice underneath the corset. The preparation of this case will be found in the Museum of University College Hospital. Such cases ought to encourage us to be patient with abscesses of this kind, and to try prolonged rest before evacuation, unless, indeed, we are of those who fear tubercular infection from them.

But when these collections are manifestly increasing rapidly, or are approaching the surface, even slowly, it is well to open them early. Two methods are before us: they may either be aspirated, or opened with the knife, or cautery, as recommended by those who believe in the infective power of strumous pus: the older methods of opening such abscesses, by means of caustics, are not now in favour. The aspirator is, however, not suited to all cases: so long as the contents are fairly fluid, and free from caseous material, or fibrinous shreds, they may be easily and safely evacuated with it. But when, as is often the case with spinal disease, the pus contains much solid matter, the needle is commonly choked with it, long before all the fluid is removed. There are, however, cases where one or two aspirations will suffice for a small collection, which is no longer fed by disease above, in which case any residue may be absorbed. But, with larger abscesses, from caries, it is our common experience that, when they have been emptied once or twice with the aspirator, so much debris has gravitated to the bottom of the sac that the needle is at once blocked on entering, no matter where we puncture. Again, if anything but one of the smallest needles is used, a little of the caseous matter may be drawn into the track of the needle, during the removal of the latter, and may here lead to irritation, resulting in the formation of a fistulous opening of the abscess after some weeks. This I have noticed, even where the parts traversed by the needle were very thick. We have, then, the choice between either leaving the collection to itself or clearing it out through an incision. If the latter line is adopted, we shall notice, at first, an escape of large quantities of curdy matter, followed by thin serous pus. And, if the strictest antiseptic precautions have been employed at the same time, the case may heal, after a shorter or longer period, with only a trifling discharge of serum at each dressing, but no true pus after the first incision. Such a result was extremely rare in the days before rules of absolute cleanliness had been, as it were, formulated by Prof. Lister, even when psoas abscesses were opened by the most skilful surgeons. It was then almost the rule for the flow of the pus to increase a day or two after the abscess had been opened, and to become more and more abundant, while the temperature rose and other signs of fever set in, until, sooner or

later, death resulted from exhaustion or septic mischief. And, even if no septic complication took place, the prolonged suppurative drain eventually led to amyloid disease of internal organs in most cases. Everyone who listened to Sir James Paget's remarks in the discussion on Antiseptic Surgery which took place at St. Thomas's Hospital not long since, must have been struck with his experience on this point, which may be held, from its great extent and varied nature, to be a standard one. He said that he could not recall to his mind any case in which an extensive psoas abscess had either burst of itself, or been opened by the older methods, which had ultimately recovered. All died, within shorter or longer periods, of exhaustion or sepsis. But, though the method of dressing, as at present advised by Prof. Lister in such cases, has such vast advantages over the older modes, its weak points must not be overlooked, if we are to do justice to our patient and to the method itself. The difficulty of retaining the present gauze packing in close contact with the body everywhere for a wide distance round the wound into the psoas abscess is one of these. If the patient be confined to bed, the difficulty is less, especially where elastic bandages are used over all; but, if he get up, and move about, is almost insurmountable with the present form of dressing. This has a great tendency to become caked and matted together to such a degree, during the movements of the limb, that it soon forms little more than a loose shell, under which air has often free access to the part, and to the discharges in the dressing, which then readily putrefy. But confinement to bed for long periods is always undesirable, as we have seen. And yet the most rigid antiseptic treatment must be persisted in for extended periods—namely, as long as open sinuses exist—if we are to exclude imminent risks. And such small sinuses often remain long after the patient might, with advantage, be up and about, with the support of a plaster corset. It remains, then, for the future, to give us a perfectly antiseptic and absorbent dressing, soft and elastic enough to follow all the movements of the parts it embraces, without caking or admitting air and other impurities underneath. In such a dressing a patient with an open psoas abscess might be kept upon his feet, in the enjoyment of fresh air and moderate exercise, with less risk than, with the usual gauze dressing, we are forced to admit exists. The following case illustrates this point:—

A railway porter, aged 20, came to the author at University College Hospital, with marked spinal caries and psoas abscess, of the existence of both of which he was unaware, having been about his work almost up to date. He was treated as an out-patient for several months with the plaster corset and aspiration of the abscess at intervals, as much as 30 and 40 ozs. of fluid being drawn off at a time. Finally as the debris increased in the fundus of the sac, and blocked the needle on each attempt to aspirate, he was admitted as an in-patient, with a view to having all the contents, fluid and solid, evacuated at once by incision under carbolic spray, &c. This was done, and much fibrinous and curdy matter removed. After many weeks in bed the man appeared so much better, that it was thought by the surgeon in charge of the case that he might leave the hospital and become an out-patient again. He was therefore placed once more in a plaster corset, with the usual Listerian dressing applied with every care, and was sent home, the wound being quite aseptic. When, however, he appeared in my department a few days later the dressing was loose, displaced and foul, and the man appeared so ill that I at once readmitted him. The wound was then found by those who dressed him to be distinctly fetid and infected, and, to be brief, the patient died a few days later of acute septicaemia contracted through it.

In this case, had the gauze dressing done its work during the short time the patient was in his own home (he was a quiet, steady man too), as it had done while in hospital, he would probably have escaped the infection of his wound. Even the quiet walking about there, however, had loosened it, and so permitted access of air to the discharges in the dressing and abscess, with consequent sepsis in its worst form. Most surgeons have seen cases of the same kind.

When these collections have unfortunately opened spontaneously before we see them, it is still well to try every precaution of cleanliness to keep or render them aseptic. Injections of solutions of chloride of zinc are perhaps the most reliable in such cases, with antiseptic packing of medicated wool, jute, or gauze, over the wound to exclude the air and absorb and disinfect the secretions.

Spinal abscesses pointing on the inner surfaces of the body, as, for instance, in the

pharynx or rectum, require less elaborate precautions against septic infection. In the first situation they should (after thorough cleansing of the part with antiseptic gargles) be opened as soon as they produce inconvenience in swallowing or breathing by a *short* vertical incision in the middle line. This will allow the pus to escape slowly and not in a sudden gush, which might carry it into the air-passages and produce suffocation or infective inflammation in the lungs, supposing the patient to escape the first danger. When this opening has fairly drained the abscess, it may be enlarged somewhat for the removal of possible debris. After this cleansing gargles, especially that of chlorate of potash, should be freely used. In the case of an abscess pointing towards the rectum, there need be no hurry in opening it. It is not likely to give rise to any troublesome pressure symptoms, and may usually be allowed to burst of itself. If opened by the surgeon, the rectum should be thoroughly emptied and cleansed beforehand by enemata.

The *prognosis* in cases of spinal disease involves so many considerations that it is difficult to speak definitely on the point. Hereditary predisposition to struma (or, as it will probably for the future be called, to tuberculosis) appears to be the most weighty determining factor. The age at which the disease commences is the next. For, when an affection of the spine begins in very early life, it may, on the one hand, be taken as a sign of the existence of an inherent susceptibility to such morbid processes, and on the other, the general feeble vitality of the tissues at this period renders resistance and repair difficult. The social conditions of our patient have also a strong influence upon our prognosis. Among the well-to-do and wealthy who can command the best hygienic surroundings, and skilled surgical care, deformity, or death, are less likely than among the masses, although scrofula, 'the king's-evil,' is met with amongst high and low. The risks both of deformity and death are increased enormously by neglect of the local and general conditions in their earliest stages, and become imminent when abscess has formed, or, worse, has opened.

SOME UNUSUAL FORMS OF SPINAL CARIES.

ATLO-AXIAL DISEASE.

Disease of the first two vertebrae requires now some special attention, not only on account of the important structures covered by these bones, and liable to be involved in their injury, but also because it differs in some remarkable respects from that of the other parts of the column.

In the first place, it is apparently a comparatively rare disease now. Thus, for instance, in the ten years 1871-80 inclusive, there is no mention of a single case of atlo-axial disease having been treated in University College Hospital, in the very careful annual reports of the Surgical Registrars, although in these may be found accurate notes of 170 cases, including all the other different forms of spinal caries, with records of all the necropsies performed within that period. Nor do I find a single instance of this affection among the notes now before me of fifty of my own cases of caries of the spine treated as out-patients at University College within the last few years. Again, in the 'Transactions of the Path. Soc.' for twenty-five years, 1849-74 inclusive, the disease has only been brought under notice five times in four of its volumes, only eight cases being presented for consideration.

In former times it would appear to have been noticed more frequently, perhaps because syphilis was allowed then to run on unchecked for longer periods, or was treated too freely with mercury. Thus Rust¹ saw thirteen cases himself (among which he had an opportunity of performing nine necropsies), and other of the older authors appear to have been more familiar with the disease than we are at present.

Again, it differs from the commoner forms of disease in being met with in adult life in a large proportion of instances. Thus, in twenty-four cases I have been able to collect, in which the age is indicated, only six were under twenty years of age (and two of these had reached eighteen) before the disease had manifested itself, while

¹ *Arthro-Kakologie*, 1817, p. 76.

eighteen were adults. Indeed, it may develop in the aged, as is shown by a very remarkable case recorded by Dr. Ogle,¹ where the patient (a very reverend ecclesiastic) had reached the age of 73 before the process began. Further, commencing thus in the adult, the causes of origin are apparently different from those operating in the commoner forms of spinal disease. Then it appears in many cases much more distinctly traceable to injury, and to occur thus in persons, to all appearance, in good health, without any scrofulous tendencies. Then it appears capable here of advancing very rapidly in destructive change, and, under treatment, of repairing itself as rapidly and perfectly.² Again, the process is more manifestly due here than lower down, in some instances, to syphilis,³ or the abuse of mercury for the cure of the latter,⁴ this syphilitic disease starting in the pharynx or in the vertebræ themselves. Finally, the process itself seems to affect the joint-surfaces of these bones more frequently than the anterior segment. These are all points which offer a contrast to the forms of disease usually met with lower down the column. And, in studying these diseases and the records of cases observed by others, the suspicion is almost forced upon one that syphilis is much more frequently a cause of spinal caries in the adult than is commonly supposed,⁵ and that this is especially true of the atlo-axial form.

The latter form of disease is not so common that one can draw very positive deductions from the published cases. Thus Lawrence states that 'it was hardly mentioned by English writers in his time, while by most it was almost completely ignored.' But such records as are published can hardly be read carefully without suggesting, at all events, the above conclusion.

That syphilitic deposits can give rise to spinal caries of the most palpable kind, without the syphilitic characteristics of the lesion being lost or masked, the following case amply shows. It may be cited here with advantage, although the part affected was not high up in the column. The very close attention which is now being given to syphilitic lesions in all the tissues of the body can hardly fail before long to show us how far such cases have a bearing upon the whole question of caries of the spine.

A man, æt. 50, tall and well developed, but in very bad health, was admitted into the Hôpital St. Louis, in July, 1870, under the care of Professor Fournier. He had been losing health for some time, and suffering from pains in the loins and lower limbs. Examination showed marked evidence of syphilis of long standing, e.g. syphilitic sarcocele, ten cutaneous gummata, as also in the muscles, and a gummosus ulceration of the great toe, also a macula on the thigh. In spite of treatment, this man's condition soon became worse and worse, and he died in October, 1870.⁶

At the necropsy, the syphilitic nature of the lesions alluded to was proved, and others were found, e.g. characteristic cicatrices on the spleen, gumma of the fourth lumbar nerve, 'lastly multiple and considerable lesions of Pott's Disease, affecting the lumbar

FIG. 89. — Vertical Antero-posterior section of Lumbar Spines, showing deposit of gumma in the back part of the third and fourth. (After Fournier)

The deposit is softening at its centre, and its products are working towards the posterior common ligament. There was also gummatous deposit in the roots of the nerves given off here.

⁵ While this article is going to press, I find that the same idea as to the probably frequent syphilitic origin of spinal caries, when it occurs late in life, has struck Mr. Furneaux Jordan from observation of cases. (*See Med. Times and Gazette*, March, 1867.)

⁶ Fournier, *Annal. de Dermat. et de Syph.* Jan, 1881.

column, especially the third, fourth, and fifth vertebræ of that region.' These consisted of 'denudations of bones, thickening or destruction of the periosteal and ligamentous structures, sclerosing osteitis with caseous and purulent infiltration, almost complete destruction of the intervertebral fibro-cartilage, and a vast hollow mass in the lumbar column, also an abscess in each psoas muscle, &c. &c.' The state of the vertebræ is well shown in fig. 89.

A careful microscopic examination showed the deposit in these bones to be clearly gumma in various stages of degeneration; also that there were many gummatous nodules in the nerves passing off from this region. In fig. 89 it may be noticed, as in fig. 84, that the disease lies on the posterior aspect of the bodies where any injury would be most unlikely to affect the bone. Nor was there any history of injury in either case, or any reason to suppose that such had taken place. The disease had

FIG. 90.

The girl, aged 15, from whom the drawing was taken, had continued in her situation as a domestic servant till three weeks before her admission into the hospital; at which time the neck was distorted as represented in the figure. The disease had apparently commenced four months previously, but it had caused so little pain or inconvenience, that she had not been obliged to give up her work during its progress. She complained of pain darting from the swelling in the neck upward to the crown of the head, and downward over the shoulders, and along the arms. She had also slight incontinence of urine. The most prominent part of the swelling in the neck was formed by the spinous process of the axis, above which, and between it and the occiput, a distinct hollow could be felt. Chiefly by rest and counter-irritants, she improved so much that in six weeks she was discharged. But three weeks afterwards, she was readmitted on account of an aggravation of the former symptoms, and there being a weakness of the lower extremities, which caused them to sink under her when she attempted to walk. In a month she was sufficiently recovered to be sent to a convalescent hospital at the seaside. She subsequently called various times at the hospital, to show that she had regained her strength completely. A cast from the neck is in the Museum of the Middlesex Hospital.

manifestly originated in both instances in the breaking down of a special deposit infiltrating the osseous tissue of the part.

The *symptoms* of atlo-axial disease, upon which we have to rely in the earlier stages, are purely subjective. These require to be borne carefully in mind; for if anything is to be done for the complaint, it must be done early. Probably the best description of these symptoms extant is that of Rust (*l.c.* §12). The perusal of the original, upon which I draw largely, in the following lines, will amply repay the student.

The first evidence of the affection will be pain in the neck, especially at night. This is aggravated by bad weather, by swallowing large morsels, and by deep

inspiration. At this time there may be no trace of anything objective, either in the pharynx or externally, and the condition may therefore be easily mistaken for rheumatism. Many patients refer all their pain to the neighbourhood of the larynx. A little later the movements of the head become painful, especially lateral flexion towards one or other shoulder. This pain, too, is referred often to the larynx (sometimes the scapula), and is described as stretching or tearing on one side. A careful examination with the finger pressed down upon the first two vertebræ will now probably discover an acute tenderness, though there is still no external sign of disease.

From this on the affection usually progresses rapidly if left alone. In addition to great aggravation of the subjective symptoms alluded to, especially pain in the occipital region on movement and on pressure, leading to fixation of the whole neck, the head will begin to sink forwards and usually a little towards one shoulder (fig. 90). This may be towards the side least affected, and is due probably to the desire of the patient to relieve the diseased side from the weight of the head. But Rust gives a different explanation in alluding to the fact that in nine autopsies he had found the left side of the bone most diseased in seven cases, the right only in two. If both sides are equally affected, the head simply drops forwards. Soon after this a peculiar fulness will be noticed in the middle line behind, just under the occipital bone, in which the spinous process of the axis, not usually felt, is now apparent. This is due in part to the shifting forwards of the head, and in part to inflammatory œdema. Anxiety in the patient's expression of face is now very manifest, especially when the slightest movement of the body is called for, when it becomes necessary to fix the head, not only by its proper muscles, but even in many cases with the hands placed on both sides. If the disease now progress further, the head glides slowly forwards on the atlas, until sooner or later the medulla oblongata is compressed by the odontoid process of the axis, partial or complete paralysis resulting in many cases. Again, pus may collect in front of the dura mater of the cord, and so produce compression (Wigan's case, quoted by Lawrence); or meningitis may be set up either with the cranium or canal. Again, the diseased ligaments of the odontoid, or the latter itself, suddenly giving way during some slight increase of strain, the process may fall backwards and compresses the cord, producing instantaneous death (Powell; Hilton, *l.c.*) These are the chief dangers to be dreaded, but by treating the cases early they can be averted. It is remarkable, however, to what an extent the cord may be compressed here without any damage to its functions, and also how completely these may be restored after having been for a long time almost entirely suspended. This is plainly shown by several of the cases alluded to. The extent, too, to which the canal may be reduced in its antero-posterior diameter without suspending life is almost incredible, until we examine such specimens as those exhibited by Sir J. Paget and Mr. Shaw,¹ where the odontoid had approached within two lines in one, and $\frac{1}{10}$ of an inch in the other of the posterior wall of the canal (fig. 92).

As to the peculiar conditions of the cord, produced by pressure or inflammation, and the constitutional conditions to which they give rise, they need not be alluded to here, as they are treated of in the article on INJURIES OF THE SPINE, and are alluded to as far as necessary at pp. 409 *et seq.*

The treatment of atlo-axial disease is conducted upon the principles which guide us elsewhere. Rest for the part is our great aim, and may be secured by placing the patient in the recumbent position with sand-bags at either side of the head to steady it (Hilton), and prevent any of the untoward accidents of displacement, or the use of Sayre's Plaster of Paris Corset and Jury Mast. This latter plan has the advantage of admitting of exercise of the body while relieving the diseased bones of the weight of the head. As to internal remedies, those already alluded to (p. 410) are called for. But, in addition to these, it is probably desirable to resort to the cautious use of mercury in the case of young adults, even though there be no direct evidence of the disease being due to syphilis. But where there is any history of this, either mercury

¹ *Med.-Chir. Trans.* vol. xxxi. p. 289.

or iodide of potassium should be used for a time, the latter preferably in older individuals and asthenic cases, and combined with tonics and cod-liver oil.

The *prognosis* with this disease is not now considered so grave as was formerly the case. Thus Rust, and others of his day, regarded it as almost inevitably fatal, while since his time many instances of recovery, as proved by careful examination,

FIG. 91.—Atlo-axial Disease. (Figure from specimen in Middlesex Hospital Museum.)

a, a, portion of occipital bone, in proper relation to atlas; b, b, section of atlas. From destruction of the ligaments of the atlo-axial articulations, the atlas has slid forward, borne by the weight of the head, and has carried the odontoid process of the axis with it, c, odontoid process of axis: loosened at its base by disease it has been carried forward in connection with the atlas; d, d, section of axis, its odontoid process detached: its articulations with the atlas, and with the body of third vertebra, and its body all much diseased; the great projection backward of the spinous process in reference to the occiput and atlas, is a result of the gliding forward of the latter. Within its canal the spinal cord is seen bent at an obtuse angle, the consequence of the portion contained in the foramen magnum and atlas being carried forward, while that in the axis has been stationary.

Case. The patient, a butler past the middle age, and corpulent, had for some time stiffness in the neck, with pains in the head and arms, supposed to be rheumatic. When seen by the writer, a large swelling extended from the upper third of the neck behind, to the highest part of the occiput, concealing the form of all the bones which it covered, except the spinous process of the axis, which appeared unduly prominent. He could perform the nodding, but not the rotating motion, of the neck. The vertical axis of the head was advanced perceptibly too far forward, in comparison with the vertical axis of the neck, the effect apparently of the head having been transported to the front slightly beyond its proper plane in relation to the spine. The disease was seen to be atlo-axial; and he was removed to the hospital. Progressive paraplegia soon commenced, and it proceeded downward; first one arm became weak and then paralyzed; shortly afterwards, the other also became weak and then paralyzed; and the lower extremities followed the same successive course. But before the legs were paralyzed by a severe attack of bronchitis.

FIG. 92.

The specimen from which this figure was taken was removed from the body of a man found dead in the streets. There was fracture at the base of the skull, all round and at a short distance from the foramen magnum; the boundaries of the fracture being seen in the figure. a, a, portion of occipital bone, insulated by the fracture; b, anterior tubercle, on anterior arch of atlas; c, posterior tubercle, on posterior arch of axis; d, odontoid process of axis. Its situation corresponds nearly to the centre of the vertebral canal at the level of the foramen magnum and atlas, e, body of spinous process of axis. About three-fifths of the articulating surfaces of the atlas have been displaced forward on the corresponding surfaces of this bone, thereby accounting for the projection anteriorly of the front segment of the atlas. f, spinous process of axis. The posterior segment of the ring of the atlas crosses the canal of the axis nearly in its middle. The distance between the posterior surface of the odontoid process, and anterior surface of the posterior arch of the atlas (the antero-posterior diameter of the vertebral canal), measures from a third to a quarter of an inch; that between the odontoid process and the anterior arch of the atlas, at the original sites of their articular facets, is five-eighths of an inch. The space between these points is traversed by an irregularly cylindrical beam of bone which unites the two surfaces: this new growth of bone is not visible in the drawing, but it had obviously been formed during the process of displacement of the atlas upon the axis, and attests the slow rate at which it had taken place. For a more detailed description of the specimen, accompanied with a drawing representing it in a different view, see 'Med.-Chir. Trans.' vol. xxxi. p. 289.

and clinical post-mortem, have been placed on record by the most competent observers (Hilton's, Paget's, Shaw's, Wood's, Keate's, Wade's cases, &c.) The whole question turns upon the possibility of recognising the nature of the case very early, and then securing rest for the head and diseased bones, while the patient's hygienic surroundings are rendered as good as possible. With these conditions recovery will usually take place, especially among adults, but of course with ankylosis of the diseased bones.

Sometimes large portions of the latter are necrosed and cast off through the pharyngeal wall, but this need not necessarily interfere with perfect recovery. This is well illustrated by the cases of Mr. Wade and Mr. Keate, in both of which a large portion of the atlas, including its articular facet for the odontoid process, came away through the posterior wall of the pharynx. In the last case 'the lower surface of the basilar process, including the lunated border of the foramen,' was also exfoliated a month later. Both these cases recovered their former health subsequently, but it must be noted that the disease in both these instances was manifestly due to syphilis, either of the pharynx or bone itself, or to the abuse of mercury employed for its cure.

Among the unusual forms of spinal disease may be mentioned, finally, one in which we are unable to discover anything objective to account for the very severe subjective symptoms present. This is, that intense pain in one or other part of the spinal column occasionally complained of, for which the most careful examination into the patient's history, and the actual condition of the part itself, fails to discover any cause. This is what was described by Sir B. Brodie and older writers under the name of 'hysterical neuralgia,' seeing that it had been noticed more frequently among females with hysterical tendencies than among any other class of patients. But more extended study will probably show that, like the 'nervous mimics' of disease in other parts of the body, this in the spine is by no means confined to females, but is met among the neurotic of both sexes.

Referring the reader for general consideration of nervous mimicry to the paragraph devoted to it in the essay on DISEASES OF JOINTS, it is only necessary to briefly point out some few points regarding mimic disease of the spine, and how it differs from the real affection.

Intense pain is sometimes complained of at one particular spot in the column, usually near one of the spinous processes, whether cervical, dorsal, or lumbar. It is keen and boring, as though a nail were being driven into the part. It is usually referred to some violence, but, on inquiry, there may be no clear history of any injury adequate to produce real disease. The patient will assert that this pain is constant, is much aggravated by pressure or movement, and, to avoid all suffering, will lie for long periods confined to bed.

Such cases call for the utmost care and study, lest true disease of the spine in its earliest, and therefore most manageable, stage should be overlooked.

Attention to the following points will be of most value in coming to a conclusion.

There is usually a history of injury, but, if inquired into, it is found to be quite inadequate to produce a condition such as that complained of. The column is not rigid at the spot complained of, as would be the case even with the earliest inflammatory affections. And, although the sufferers will state that the pain is greatly increased on movement, still they will usually wince or writhe when the seat of pain is handled in a way which shows clearly that this is not the case, and that the movements here are as free as at any other part of the column. The increase of suffering, too, complained of on gentle pressure on the spot, is out of all proportion to what is felt in cases of real disease. Again, if the patient's attention be fully engaged on something else during the examination of the part by pressure or rotation of the trunk, it will be noticed usually that both can be pushed to an extreme degree, without eliciting much expression of suffering. Then, when left to themselves, these patients, when unnoticed, will turn in bed, sit up, or flex the spine with an ease which one with true structural disease would never exhibit.

Sometimes this condition is complicated with hysterical paraplegia, giving the case, at first sight, a grave aspect. But, knowing that in the vast majority of cases paraplegia with true caries does not come on until great destruction of the column has taken place, with consequent deformity, we are reassured in such cases by the absence of the latter. The purely medical features of the case, too, will help us materially to a correct diagnosis.

DISEASES OF THE SPINE.

PART II.

SCOLIOSIS, OR LATERAL CURVATURE.

THE above titles are given to a distortion of the chest properly, which originates in twisting of the spine. The term 'Scoliosis' (*σκολιός*, tortuous) has the merit of brevity, and is largely used on the Continent.

The degree of deformity of the chest, shoulders, hips, or trunk in general, caused by the combined incurvation and twisting of the spine, is, in many cases, extremely great. Patients in whom the distortion is taking place, although often weakly, do not suffer at the outset from any serious illness. An important distinction is to be drawn in regard to the causes producing them, between it and angular deformity of the spine from caries, and between them both and curvature of the bones generally, including the spine, from rickets.¹

The progress which scoliosis makes at first, in correspondence with the youthfulness of the patient, is commonly rapid; in proportion as the bones become more consolidated with increasing years, it is slower; and at about seventeen, when the skeleton has nearly reached maturity, it may become for some time stationary, and not unfrequently aggravated in later life.

A distinguishing characteristic of scoliosis is that it is incomparably more frequent in girls than boys.

Moreover, it is met with among the daughters of the well-to-do in tenfold greater numbers than in those of the poor.

Often an hereditary predisposition has been made out; hence arises a question whether it may not often be hereditary, when no history of it is obtainable, especially as Guérin² has recently, from his dissections of congenitally affected infants, pointed out that the direction and sides of the curves are often the same as in adolescent non-congenital cases.

The chief peculiarity in the construction of the vertebral column which favours incurvation is that, although its chief office is to support the superincumbent weight, it is at the same time flexible. Again, this many-jointed pillar, instead of resting on a fixed foundation, is reared upon one which is constantly changing its level. The pelvis, upon which the spine is erected, is poised on the globular heads of the thigh-bones, and it rolls and pitches at various angles according to the positions of the limbs. The column is, therefore, in the predisposed, subject to be deflected from the perpendicular at each shifting of the base, when the weight it sustains will be thrown unequally on its articular surfaces.

The spine, at the age when it usually commences, has attained nearly its full length. That forwardness is in conformity with the development of the cord within, for the slight addition to the column which takes place later is made at the base alone; that is, below the level of the cord itself, and in the region of the 'cauda equina.' The subsequent increase in the general height is chiefly owing to the elongation of the lower extremities. But, although thus advanced in length, the ossification of the spine has not made equal progress. The cartilage is in disproportionately

¹ See Part I; also article RICKETS, vol. iii.

² *Œuvres de Jules Guérin*, 1 livr. 1860.

large quantity compared with bone. The epiphyses on the upper and under surfaces of the bodies consist chiefly of cartilage. The texture of the bodies themselves is porous and spongy, and their surfaces in relation with the epiphyses, instead of being flat, are partly convex and rounded as in infancy; the pedicles, laminae, and processes of the posterior segments of the vertebrae, besides being deficient in density, are imperfectly moulded in shape; and the borders of the articular facets of the oblique processes, instead of consisting of bone, are edged with cartilage.¹

The muscles which elevate the spine are distinguished both for their great number and the variety of the directions and movements in which they severally act. These provide for the prompt adjustment of the superincumbent weight to the centre of gravity, in the numerous deviations of the spine from the straight line in the ordinary motions of the frame. It may be added that these muscles are inserted into the vertebrae close to their centres of motion; they therefore act upon them at a mechanical disadvantage; but the power thus lost is amply compensated for by the assistance which they derive from the elasticity of the column.

For keeping the spine in a state of average strength, it is necessary that a proper amount of varied exercise should be allowed. But in the case of young females of the class of society in which this curvature is most common, certain circumstances tend to prevent them from obtaining it. The age at which the deformity commences coincides with that at which a notable change takes place both in the physical and moral constitution of a female. As the period of puberty approaches, a girl begins to show tokens of her feminine character. Having been previously, like her brothers, full of animal spirits and fond of romping games, she spontaneously takes to sedentary occupations. The time given to learning and accomplishments is disproportionately great compared to that allotted to the bodily graces and preserving the health. In some instances, however, parents have insisted that the girl had continued to be a regular 'tom-boy.' Were these instances hereditary?

When the muscles lose power, the loss is felt beyond their own sphere. It is a law of the animal economy that an intimate relation should exist between the muscles which originate force and the bones and joints which bear the brunt of it. The mutual connection may be illustrated by the case of the trained boxer. In proportion as the power of his muscles increases, the density of the bones and tenacity of the ligaments are augmented. Were it otherwise, and the muscles of the arms acquire great strength, while the humerus and the ligaments of the elbow, for example, were relatively weak, he would be in danger of fracturing the one or dislocating the other when he inflicted a heavy blow with his fist on his adversary's head. And the converse is equally true; in proportion as the muscles diminish in power, the bones become less solid, and the ligaments less capable of resistance. Applying the law to the state of the bones and joints of the spine, it will be seen that when the muscles have been debilitated by inaction, a corresponding degeneration of the internal structure of the vertebrae and of the ligaments will ensue.

On viewing the mechanism by which the apparently inconsistent qualities of stability and mobility are combined in the spine, it will be observed that the vertebrae rest and move upon each other only at three distinct surfaces of contact, above and below respectively. These are, anteriorly, the fibro-cartilaginous articulations of the bodies; and, latero-posteriorly, the articulations of the wedge-shaped, oblique, or articular processes. When the spine is straight, the pressure of the superincumbent weight will be divided equally among those surfaces; and no damage need be apprehended. But it will be otherwise when the column is inclined to either side, and is allowed to remain curved. The effect which will be produced on the concave side of the curve will differ from that produced on the convex; but both will tend, each in its own way, to render the bend a permanent one. When the spine yields on one side, it is obvious that the weight of the body will fall exclusively on the articulations situated on the side on which it yields, and that a convergence of the adjoining

¹ Two preparations of the spine, preserved in spirits, showing the extent of ossification of its different parts at the age when lateral curvature commences, are contained in the Museum of the Middlesex Hospital.

structures will take place; hence the force acting on this, the concave side, will be one of compression. Again, it is obvious that the effect of the inclination on the articulations of the convex side will be that of separating the surfaces, and producing a divergence of the connecting structures: accordingly, the force here will be one of stretching and elongation. Now it is important for our subject to observe the changes which will be produced in the articulations by the operation of these distinct forces. By the compression acting on the concave side, there will be, as the first change, a tendency of the surfaces to glide past each other beyond normal bounds, in a

FIG. 93.—Unpublished diagram of Mr. A. Shaw, intended to illustrate the effect of resting mainly on the right leg—the normally stronger leg.

a, tensor vaginae femoris; h, the same muscle in a state of relaxation; A, the left ilium lowered; u, the right ilium raised; c n, line of corresponding tendency of spinal column; v g, line towards which the trunk is instinctively inclined in order to obviate the tendency of c towards the ground. The dark curved line which springs from the junction of the lines c a represents below the ordinary lumbar curve to the left, and above the direction of the dorsal region to the right, in order to recover the centre of gravity.

FIG. 94.—Back view of average severe Scoliosis.

[From Mr. Alexander Shaw's original dissections and drawings. They represent the stage at which the greater number of cases of 'lateral curvature' are first brought for consultation, assumed to have been recently discovered by the parents, but which, doubtless, as a rule have already been two or more years making insidious progress. It may be remarked of this distortion, as of some others, that it often makes an alarming sudden progress after two or three months of some exhausting pursuits, such as long daily rides on horseback, over-long walks, and standing during an autumnal vacation, or the too early permitted indulgence in late hours, at the age of accelerated growth, and of approaching puberty, when any fresh natural risks of disturbance in the economy should be guarded against.]

downward converging direction; and subsequently the bony structures will come into contact and undergo absorption. By the force of dilatation, acting on the convex side, the ligaments will be overstretched in an eccentric or expanding direction. Meanwhile the bony surfaces enlarge on the convex side when relieved from the normal pressure, through continuance of growth, thus adapting themselves to the change of relation, in a manner similar to that which we have described as taking place in club-foot under similar circumstances. The general result will be that the vertebrae included in the curve will receive a bias to incline sideways, first, from the

weakness of their articulations, and next, from the unequal changes in their bony surfaces and processes. And such, it may be added, constitutes the starting-point of organic mischief.

General appearances.—The deformity varies as to degree and relative place in the spine; but a typical form can be recognised in all cases, proving their identity in origin and kind. According to it, two curvatures coexist; one above the other, and one balancing or opposing the other; so that together they describe a serpentine line, like the italic letter *f*. The superior curve is situated more or less high in the dorsal region; the inferior occupies the lumbar. (See figs. 94 and 95).

In general the curvatures just mentioned are the only ones. But, if the dorsal be lower than usual, a curve in an opposite direction, formed of upper dorsal and

FIG. 95.—Illustrative of the gradual production of the permanent compensatory Dorsal curve, simultaneously with the Lumbar curve.

FIG. 95 represents an average case of Scoliosis, or rotatory lateral, or what is commonly called lateral, curvature of the spine (from a photograph).

The patient is supposed to be walking in a straight direction, or seated on an even seat, the line of the pelvis A B being horizontal. A curve having been established at M, the head, if the spine were rigid, would fall to K. It is instinctively swayed to L, thereby causing the dorsal curve. Compare fig. 84.

lower cervical vertebrae, will probably be found. Again, in the sacrum, a slight diminution of breath on one side may represent the presence of a curve there, the counterpart of that above in the lumbar region.

The course which the different curves follow, in reference to the sides of the body towards which they respectively bend, is so uniformly the same in a large majority of cases, that it appears governed by a general law. Thus, looking first to the lumbar curve, experience shows that, in about nine patients out of ten, the column is deflected from its base to the left side, and that it is then inclined to the right; thereby forming an arc; the concavity of which is on the right. As to the dorsal

curve, the direction it takes is determined by that of its fellow; for, as the one is placed counter to the other, the arc it describes will be concave on the left. In those exceptional cases in which the above rule is reversed, the concavity of the lower looks to the left, and that of the higher to the right.

But the curvatures do not consist simply of lateral archings of the spine. Combined with each curve to either side, there is a vertical twist in the column, consequent on a partial rotation of the vertebræ on their long axis. And the direction of the contortion in reference to the curve is constantly the same; that is, the revolution of the vertebræ is always such, that their sides corresponding to the concavity are wheeled forward, and those on the convex side backward. It follows that, as the spine is bent laterally, and also contorted longitudinally in the upper curve, and is also similarly bent and rotated in the lower, but in a contrary direction, a spiral or corkscrew condition will be produced; or the column will present an appearance not unlike what might be supposed to result from taking it, when soft, at both ends, and twisting it between the two hands as a washer-woman wrings a wet cloth.

Fig. 97.

In this schematic figure of a scoliotic spine, M. A. Shaw exhibits at a glance the greater straightness of the spinous processes than of the bodies.

Mr. Alexander Shaw, the author of the article on this curvature in the former editions of this work, to whom science and ourselves are much indebted for his accurate and original researches, was the first, we believe, to point out that, in estimating the amount of distortion, the surgeon should not be guided by the degree of departure from the perpendicular line of the tips of the spinous processes, as he explicitly says in the succeeding paragraph:—

‘Here it may be convenient to notice a source of deception connected with the contortion, to be guarded against in examining a young person’s spine for the detection of lateral curvature. The ordinary way of proceeding is for the surgeon to run his finger down the ridge of spinous processes, and by dotting the tip of each in its turn with ink, obtain a line representing the curves. To prove the fallacy of the method the adjoining diagram is introduced. The bold, outer, curved line is intended to show the course of the bodies of the vertebræ; the faint dotted one that of the apices of the spinous processes. It will be seen that the combined effect of the twofold incurvations and contortions in the dorsal and lumbar regions is to make the tips of the spinous processes, above and below, range themselves into a line which is nearly straight. That result is owing, first, to the fact which has been stated—that in the contortion accompanying each curve, the spinous processes point toward the concave side; and, secondly, to the concave aspects of both curves, upper and lower, being turned in common to the median line of the body. It follows, of course, from the apices of the processes in each equally approaching the median line, that the joint curvature which they describe will deviate but slightly from a straight line.’

Formation of the curvatures.—Anatomical reasons point to the probability that the lumbar curve is first formed. 1. The vertebræ of that region, being situated at the bottom of the column, have the whole superincumbent weight accumulated on them. 2. This part of the spine is highly flexible, decidedly more so than the dorsal. 3. Owing to the unstable character of the base—the pelvis—on which the lumbar vertebræ rest, they are more prone than others to be deflected from the perpendicular. 4. The lumbar, unlike the dorsal vertebræ, derive no support from the clavicle, sternum, and the ribs. On the contrary, the bodies of the lumbar vertebræ have only such support in front as may be afforded by the abdominal muscles, and the intervening, more or less, soft and yielding viscera. In the healthy and robust, accustomed to due physiological activity, the tonicity of these muscles, and the due robustness of fibrous and osseous structures, oppose anterior and lateral yielding of the bodies.

The question may therefore be asked, If there be any particular position into which the lumbar vertebræ are liable to be habitually placed which might expose them to become permanently curved? Now, there is a particular posture into which persons have an instinctive tendency to place themselves for the sake of getting relief when fatigued in their lower limbs, either from walking or standing; and while indulged in, the spine is bent laterally at the loins. The attitude is known in the drill of soldiers as the position of 'standing at ease.' And a special mechanism is introduced into the human frame in connection with it. The part of chief consequence in the apparatus is that strong membranous web which covers the muscles on the outside of the thigh as a sheath, and is called 'fascia lata.' This dense structure is attached extensively above to the external lip of the crest of the ilium, and is continued below into a similar fascia on the outside of the leg. The way in which the mechanism acts is as follows:—The foot of the person having been solidly fixed on the ground, with the knee extended, the pelvis, carrying the body with it, is allowed to drop into an oblique position to the opposite side. The consequence of this inclination is, that the side of the pelvis which corresponds to the leg on which the person stands is elevated. But a further result ensues: the elevation of the crest of the ilium, to which the fascia lata is attached, causes that membrane to be put into a state of tension. In other words, the expanded membrane acts the part of a ligament in restraining the pelvis from falling too far sideways; it therefore, in effect, supports the weight of the body. It may be added that, owing to the same lateral inclination of the pelvis, the head and neck of the femur are drawn outwardly from the acetabulum to the extent of putting the capsular and round ligaments on the stretch; they will therefore assist in locking the hip-joint, and fixing the pelvis. In that manner, the task of keeping the body upright is thrown off the muscles and given up to fibrous or ligamentous parts; and it follows that, as these structures are devoid of sensation, they can perform the duty without fatigue.

But what is of greatest interest in connection with the attitude is the curvature in the spine required for preserving the equilibrium. The appearance of that deviation will be best seen by observing a young person whose joints are flexible, lounging lazily on one leg. A large sweeping curve, sometimes almost a semicircle, will be found extending from the lower part of the dorsal region to the sacrum. Now, if it be admitted that the posture is one of ease, which gives relief to the muscles of the limbs when fatigued, and is, moreover, frequently indulged in, it may be granted that the curve will be prone, in a young, growing person, especially of delicate frame, to become permanent. The vertebræ, and all the structures connecting them, will be in danger of undergoing changes in their forms and relations, to accommodate themselves to the position. Supposing, therefore, that the curvature has become confirmed, and that it is situated principally in the loins, what effects may be anticipated?

It is obvious that, so long as the person in whom the curve exists can keep the pelvis poised in its oblique position, he will experience no inconvenience because the deviation is adapted to it. But the circumstances will be greatly changed when he adopts a posture in which the pelvis is necessarily horizontal. That is the case in sitting or in walking. It may therefore be expected that when a person in whom the spine has acquired a permanent bend near the base sits or walks, not only the column, but the whole superstructure reared upon it, will fall extensively to one side.

There will be remarked in most cases of advanced scoliosis more or less marked tendency to a third or cervical curve. The dotted line *c d'* (fig. 98), if continued slightly upwards and across the median line, will represent this third curve. The tendency to the third curve is shown in the living, by the head slightly leaning to one side, and being at the same time slightly rotated.

It might, perhaps, be thought that this habitual lumbar curve could be rectified by the patient exerting the muscles of the back to prop up the spine, or by poising the pelvis in a contrary line to the first. But these attempts will be unavailing for two reasons: first, they will not succeed on account of the changes in the relative dimensions of the two sides of the vertebræ, and of the connecting structures contin-

gent on their curved shape; secondly, owing to the twisting of the vertebræ which invariably accompanies the incurvation, the several processes and articular surfaces are so much altered in their relative positions that they become mutually interlocked, and the movements between them are checked or arrested. Accordingly, as the lower curve cannot be spontaneously overcome, and the equilibrium must be restored, the only alternative is the formation of a new one above it, and in counteraction of it. The spinal muscles on the convex side act on the upper part of the spine; and by gradually raising it and drawing it toward the median line, they eventually bring its summit over the seat of the centre of gravity. The muscles attached to the head

and to the shoulders contribute to adjust them also, and direct them towards their correct places. Thus the superior or dorsal curve is formed.

Causes of the rotation.—It may now be inquired into, how the twisting of the spine on its long axis, which is an invariable accompaniment of the lateral incurvation, is produced. It is about equal in degree both in the lumbar and dorsal curves, and has also a definite relation to the curves; being always directed in such a manner that the concave sides of the vertebræ are wheeled forward, and the convex, of course, backward.

It has been stated above, when advert-
ing to the surfaces and processes by which the vertebræ are articulated, that the only solid structures, as distinguished from the

FIG. 98.

A, B, oblique line of pelvis when standing on right leg; C, D, line indicative of the tendency of the trunk to fall to the left when standing on the right leg; C, D, D, curvature of spine consequent on oblique direction of the pelvis; a, b, horizontal line of pelvis, as in the posture of sitting; c, d, position towards which the spine, having become curved in the loins, is liable to fall when the pelvis is placed horizontally. The curve in the loins being permanently established, the exertions of the patient to restore the equilibrium tell only on the part of the spine above. The dotted lines c, d, c, d' indicate the line of the formation of the lumbar and dorsal curves.

FIG. 99. Diagram illustrative of the invariably simultaneous rotation of vertebræ in Scoliosis.

A, B, C, D, normal position of a normal lumbar vertebræ; a, b, c, d, rotated position of the same; X, supposed chief centre point of rotatory movement—namely, in the most compressed and absorbed articular processes of the several lumbar vertebræ, more or less, on the right side.

muscles and ligaments, which intervene to check or arrest lateral movement in them, are the articular processes. It was also shown that, when the muscular and fibrous structures were inefficient, and the spine inclined to one side, the effects produced on these processes by the pressure of the superincumbent weight differed essentially on the two sides of the column; that from the weight being received wholly on the concave side, the articular processes of that side were shortened and flattened by absorption; while, owing to the processes on the convex side escaping compression, they preserved their normal shape and size, and diverged from each other. The influence which this contrast in the rate of simultaneous twisting and absorption of the substance of the vertebræ on the two sides may have in causing lateral incurvation will be apparent when we take into view the relative position of these processes

to the central axis of the spine. They are placed postero-laterally in the vertebra. Consequently, at the same time that the column falls sideways, a rotatory movement, in a partially horizontal plane, will take place upon the articular processes of the concave side as centres or pivots; and the vertebræ will, therefore, perform a partial rotation, with their sides, which have undergone the chief destruction, pointing forwards.

Dr. Judson has contrived an ingenious and useful mode of artificially articulating the vertebral bones, very illustrative of this influence of the anatomical form of the articular processes in favouring rotation.¹

If, however, instead of a normal lumbar vertebra, we take a dorsal or lumbar vertebra from the body of an advanced scoliosis subject, as in fig. 100, we find, in

FIG. 100. The lumbar portion of a case of probably Rachitic Scoliosis seen from the left side.

a, a the almost straight line of spinous processes; *t, t, p,* the right transverse processes approximated to the spinous ridge; *T, t, p,* the left transverse processes, unduly distant from the spinous ridge, *b, b, b, b, b,* the bodies distorted anteriorly, and to the left. It will be observed also that opposite to *b, b, b, b, b* is a series of knobs or prominent elevations, each of which corresponds with each intervertebral substance. This protuberant appearance of similar displaced vertebrae has been before pointed out in rachitis.

FIG. 101.—Front view of the same specimen.

Showing the anterior bulge of lumbar vertebral bodies and their rotatory curve to the left, the irregular disposition of the transverse processes, and the protuberances at the intervertebral junctions. The drawing of this specimen has already been published without acknowledgment of its source.

addition to its observed rotation on its horizontal axis, and its hitherto described changes in form, that the relation of the transverse processes to the spinous process is much changed—the transverse and spinous process on the concave side have become approximated, say, in the lumbar vertebra, half an inch, and sometimes upwards of half an inch, the space between the spinous and transverse processes being much narrowed in the hollow side, with corresponding increased space between them on the protuberant side. This is well shown in a specimen of lumbar scoliosis obtained by Mr. L. S. Little, models of which were deposited by him at the London, and the National Orthopaedic Hospitals. The above drawings (figs. 100, 101) of it bring out

¹ Judson, *The Cause of Rotation in Lateral Curvature*, New York, 1876. This gentleman has been good enough to present to the London Hospital Museum one of the contrivances in question. It shows also the contributing share of the weight of the head and upper extremities in producing scoliosis in predisposed subjects.

well the relative straightness of the spinous ridge (see fig. 100), whilst considerable twisting and deformity of the bodies exist.

This subject would be incomplete without the addition of the following figures, published by Mr. Little, in the 'London Hospital Reports,' 1867.

The first exhibits the subject of severe scoliosis, with the dorsal muscles dissected. The gibbosity is considerable, and the consequent alteration of the proportions of the trunk and upper limbs well marked. The third figure shows the dissected skeleton with the considerable double curve; but neither the first nor third figures would give any indication of the surprising twist of the bodies, as shown in the front view of the column at No. II.

Special appearances at different curves. Trunk.—Decrease of height, and increase of breadth in the trunk generally, with consequent disproportionate length in the extremities.

Lumbar curve.—Owing to the thickness of the mass of muscles in the loins, and the natural arching of the vertebrae forward causing a hollow behind, the lumbar part of the column does not come so distinctly into view as the dorsal; hence it is not always easy to discover a curvature in it, especially at its incipient stage. The only apparent sign of there being one may consist in the waist being peculiarly

FIG. 102.—Unusual form of Dorso-lumbar Scoliosis to the right side, showing the disproportionate distortion of the bodies compared with the line of the spinous processes.

short and broad, which indicates that the lumbar vertebrae have yielded to the pressure of the superincumbent weight and become curved. To estimate the weakness of the part, the patient may be instructed first to place herself in a lounging posture; the clumsiness of the waist will then be perceptibly aggravated; but, by asking her again to make a strong effort to elevate her body, a visible improvement in the proportions of the waist will take place, which will last so long as the exertion is continued.

Supposing the deformity more advanced, the first thing perceived in the loins will be a want of symmetry between the two sides—a narrowness and fulness on the one, and an expanded sunken condilion on the other; the contrast being more apparent if the patient stand in a slouching position. Accordingly the muscles which lie upon the vertebrae on the full side will be stretched, and also thrust back, so as with the transverse processes situated beneath to form a curved, rounded swelling (see p. 429). If the twisting be considerable, the consequent displacement of the muscles may be so great that their inner margins, in relation with the vertebral ridge, will overlap the points of the spinous processes, and conceal them. As in cases of slight curvature, the fulness may not be easily recognised; the best mode of bringing it into view is to direct the patient to bend forward, as in making a bow, when the inequality will be distinctly visible.

In proportion as a lateral curve at any part of the spine becomes more acute, the accompanying rotation or twisting is increased; and the bulging at the convex side is augmented to a corresponding degree. That condition is much more visible in the dorsal (see fig. 95) than the lumbar region; yet cases have been met with, in the loins, wherein the rotation of the vertebræ on their long axis has equalled not less than a quarter of a circle in its circuit; and in which the vertebræ at the principal bend, when looked at from the back, were seen in profile instead of posteriorly.

Another effect produced upon the figure, by the lumbar curve in connection with the pelvis, may be noticed. As the vertebræ spring from the sacrum, they may incline, in the first part of their course, at such an acute angle to the left that they

FIG. 103.—Posterior view of extreme Scoliosis. (Reduced from an engraving, taken from a drawing by Sir C. Bell, in Mr. John Shaw's folio work on 'Distortions of the Spine,' favoured us with MS. explanation by Mr. Alexander Shaw.)

follow the line of the brim of the pelvis, and are in close proximity to it. The consequence of this near approach is that the boundary of the upper margin of the wing of the ilium is concealed, and the surface of that part of the region of the hip being nearly on the same level with that of the ridge of the spine, they appear merged into one. The result is, that the hip seems not only greatly enlarged, but elevated above its normal height. The sense of spinal weakness at this part is sometimes in middle-aged persons relieved apparently by the lumbar vertebræ resting upon the left ilium, or by the ribs on the right coming into contact with, and resting upon, the right ilium, as in fig. 103. The Museum of the Royal College of Surgeons of England contains a specimen of arrested scoliosis, through the deposit of bony plates along the front of the vertebral bodies.

The appearance of the lumbar region on the concave or right side of the curve presents a general contrast to that on the convex. Owing to the spine receding from its base to the left, in forming the curve, the right side has greater breadth across

than the opposite; and, owing to the column being rotated on its long axis with the right sides of the vertebræ forward, a flatness, or hollow, or even a flexure in the surface, is produced. But a notable difference between this side and the convex will be perceived, especially in the form and situation of the waist. Owing to the inclination of the spine to the left, the right side of the pelvis becomes particularly distinct, and juts out like a promontory. Consequently, this lower boundary of the waist comes conspicuously into view, and the flexure above is abnormally deep. The contraction, however, on the left, which alone corresponds to a waist, is merely a hollow in the side, from depression in the ribs, and is situated far above the level of the proper place of the waist: so that a line drawn between them would be highly oblique, instead of horizontal. The difference in form of the two sides of the waist in an average scoliosis is well shown in fig. 95.

FIG. 104.—Supposed transverse section of the Thorax about its middle: to show the displacement of the ribs consequent on the rotation of the dorsal vertebræ.

FIG. 105.—Diagram representing a supposed transverse section of the Abdomen, at the lumbar region.

Further, owing to there being a natural stoop forward at the dorsal region, the features of the distortion are rendered to a certain degree more distinct than below.

Chest.—From the upper or dorsal curve being situated in the part of the spine to which the ribs are attached, the walls of the chest are included in the deformity. Again, as the scapulæ rest on the chest, the position of the shoulders is also involved. Further, owing to there being a natural stoop forward at the dorsal region, the features of the distortion are rendered to a certain degree more distinct than below.

On examining the dorsal region of a patient in whom the deformity is incipient, the first thing to be remarked here, also, will be a want of symmetry on the two sides. Supposing the case to be one of an average kind, there will be increased fullness and elevation on the right, and contraction with depression on the left. The line of the lateral curve will, to some extent, be traced by following the course of the spinous ridge. But, in order to estimate the accompanying rotation, the elevations on each side of the ridge, corresponding to the transverse processes, must be looked to; when that upon the convexity will be found abnormally protuberant, and that upon the concavity proportionately depressed.

Attending next to the ribs: the changes in their position are twofold, depending on distinct causes. Taking the convex side first, the ribs radiate from the spine, like

the rays of a fan, so that the distal ends are separated and the intercostal spaces enlarged; but, in addition to this, they project backwards (see fig. 103). Looking next to the concave side, the ribs converge, like the spokes of a wheel concentrating to the axle, and their distal ends approximate; but, in addition, they advance forward. Hence it will be perceived how the right half of the chest, as looked on posteriorly, should be both abnormally expanded and protuberant; and the left both contracted and depressed. Again, it will be found, as might be anticipated, on turning the eye to the front, that the anterior ends of the ribs and costal cartilages are flattened or depressed on the convex or right side, and prominent on the left. The chest appears, therefore, as if the left half were moved forwards and outwards, and the right half backwards and inwards. The left mamma consequently presents more

prominently outwards than natural (see fig. 104). These changes in the directions of the ribs depend, it is obvious, on the analogous ones in the spine: the ribs being like the indicators on a dial plate, magnifying the movements at the centre. The radiation on the convex side results from the divergence of the articulating surfaces appropriated to the ribs on that aspect of the spine, connected with the lateral incurvation, and the projection posteriorly results from the rotation of the vertebræ on their long axis. A similar explanation, but with the order of the changes reversed, applies to the concave side.¹

Shoulders.—From the scapulæ being placed loosely on the summit of the chest, and retained in their places only by the muscles, and by their articulations with the clavicles, they are free to rise, sink, protrude or recede in conformity with the variations in the forms of the chest. As the upper ribs, of the convex side, which support the *right* scapula, are both elevated and directed posteriorly, the shoulder is not only raised above its ordinary level, but projected backwards: hence it is high and bulging as if enlarged, and fits closely against the side. The ribs on the concave or *left* side are pointed downwards and forwards, so as to cause a general collapse of the upper region of the chest: the scapula is thus deprived of support, and is held in its place principally by its attachment to the acromial end of the clavicle: the shoulder, therefore, falls down by its own weight and that of the arm below its proper level; it also stands off apart from the body, with a flattened and pendulous appearance. It will presently be seen that, in certain extreme cases of the deformity, in which the ribs on the convex side are wound about the vertebræ as a consequence of the contortion, that side is diminished transversely and loses its rotundity: the right scapula will then descend from its elevated position to the level of its fellow on the left. Occasionally the chest, together with the shoulders, is turned, as upon a pivot, by the wheeling round of the spine, to such a degree that its left side will face to the front and its right to the rear, to such an extent that the medullary canal can be seen into from between the ribs. A remarkable illustration of this fact is afforded by the distorted spine in the skeleton of a prematurely overgrown young giant (nearly 8 feet), preserved in the Museum of the College of Physicians at Philadelphia. The clavicles will revolve equally; and the displacement of one of these at its sternal articulation from this cause has been known to be so great, that it has pressed on the trachea, so as to threaten suffocation, and necessitate partial excision.

When lateral curvature, from neglect, becomes worse, the increase is almost always more apparent and extensive in the dorsal than in the lumbar region. With increase of gibbosity, an increase in the acuteness of the 'angles' of the ribs, with a flattening of their centres or bodies, appears. That change is obviously caused by the progress of the rotation of the vertebræ on their long axis. As the spine revolves, the ribs are drawn to it, just as a rope in machinery is coiled about a barrel in circular motion. Accordingly, in proportion as the vertebræ rotate, the proximal ends of the ribs travel backward, and, by so doing, increase the acuteness of the angles. Again, as a resistance is made to the posterior movement by the attachment of the distal ends of the ribs to the sternum, a stretching force is applied, which has the effect of straightening their arches and flattening their contour. As the contortion advances, the line of angles is carried further backward, till it forms a prominent ridge, concentric with the spinous, and more prominent. The muscles which lie in the vertebral groove are so much displaced by the twisting of the column, that their inner margins now overlap the tips of the spinous processes, and conceal them. When the deformity has proceeded thus far, the next stage in its progress is, that the proximal ends of the ribs, from their articulating heads to the angles, inclusive, are transported bodily round, in their bent condition, by the circumvolution of the column, so as to be in actual contact with the sides of the vertebræ, and to be coiled upon them. The twisting of the spine on its long axis is, of course, very great in these extreme cases—being equal, it may be estimated, in certain of the vertebræ, to nearly a quarter of a

¹ The appearances described above will be made more distinct by the patient's stooping, so as to protrude the spine and adjoining ribs; as well as by crossing the arms in front. akimbo, to draw the scapulæ forward.

circle; and at the same time that the contortion proceeds, the spine becomes more acutely bent. From these combined causes, a prominent enlargement, standing out abruptly from the centre of the back, with expanded ribs overlying the spine for its summit, is formed, constituting the hump.

Simultaneously with those changes on the convex side, equally great ones are being wrought on the concave. In proportion as the spine revolves, the sides of the vertebræ and the ribs connected with them are carried forward; and as the column bends increasingly, the articular ends of the ribs are caught and enclosed in the deep parts of the angle formed by the upper portion of the spine with the lower. Consequently, the sides of the vertebræ, more particularly the oblique processes, and the posterior halves of the ribs, undergo heavy pressure from the superincumbent weight. Hence they become extensively wasted by absorption. Large portions of the posterolateral parts of the vertebræ disappear: the intervertebral substances are greatly pinched, and the bodies present a skewed appearance. As to the ribs, they are not only huddled closely together, but may be attenuated so as to be scarcely thicker than goose-quills.

By degrees the hump may equal that which obtains in angular spinal deformity, or be even greater, with the characteristic difference that in scoliosis the disparity in size and form in the chest is apt continually to increase. It has often been said that there is no lateral yielding in angular curvature. This is true in the main, but the surgeon needs to watch the progress of angular curvature, and on the first appearance of lateral yielding take measures to check it.

It is manifest that important encroachments must have been made on the space within the chest, intended for the heart and lungs, by the changes in its parietes just described. All that part, for example, contained between the portion of the walls which had become folded about the spine, and the spine itself, on the convex side, would be lost to the pleural cavity. Again, from the contraction of the chest on the concave side, the room for the lungs would be greatly diminished. It may likewise be conceived that much embarrassment in the actions of respiration would result from the remarkable disfigurement of the ribs, particularly at their articulations. Nevertheless it is known that the various organs possess an extraordinary power of accommodating themselves, with at first little impairment of their functions. Often probably a predisposing cause of scoliosis has been the hereditary or acquired tuberculous diathesis. Some break down with early pulmonary phthisis, though less often than from previous vertebral disease. As age advances, suffering from internal disease may arise. The liver, stomach, lungs, and heart perform their functions with difficulty in the gradually increasing limited space allotted to them, organic disease of them follows, and shortens existence. We have, however, met with extreme scoliosis subjects nearly seventy years of age. In extreme cases of distortion, the compages of the thoracic and abdominal cavities present both singular irregularities, and all the viscera contained in them undergo a new moulding of their figures to adapt them to the changes. Thus the spinal cord submits to be altered both as to dimensions and shape, in accommodation to the tortuous form and abrupt angular bendings of the vertebral canal, without loss of function. On the concave sides of the curves, the intervertebral foramina become contracted and partially closed: it might be supposed that the spinal nerves would be pinched and injured in their passage through them; but experience shows that pain from this cause is an exception.¹

In the earliest stage of scoliosis, all distortion may disappear on suspension or lying down, and it is probable that, with disappearance of the outward distortion, the column has temporarily become straight.

Undue mobility at the junction of the curves, especially where the lumbar curve

¹ It is said that a formerly well-known Sussex surgeon and palæontologist, who had scoliosis with great tumour in the left lumbar region, suffered so much pain that the tumour was attributed to cancer.

ends and the dorsal begins, is often present in advanced cases, and accounts for much of the apparent improvement visible when the patient is suspended or assumes the recumbent position, though the essential morbid rotary curves remain.

Diagnosis.—The deformities within the bounds of the spine and chest, with which scoliosis is liable to be confounded, are contracted chest and spine from pleurisy (see pp. 441 and 442), and (fig. 106) angular projection of the vertebræ consequent on caries or on rickets. The better to assist diagnosis we have juxtaposed the ordinary form of angular curvature from vertebral disease and that from rickets. In determining the rachitic origin the surgeon will seek for other signs of that disease (vol. iii.) If the disease which causes the formation of the angle be seated in the dorsal region, the ribs attached to the column on each side are a bar to the spine bending sideways; but when the disease is lower, especially in the dorsi-lumbar region, there may be a slight deviation to either side, and the angular may then present some of the appearances characteristic of scoliosis. The principal distinguishing feature between them, so far as the deformity is concerned, is that rotation of the spine is an invariable accompaniment of scoliosis, and is rarely present, even in a slight degree, in angular; and as the signs of that twisting movement in the former are always recognised with ease, there ought to be no difficulty in perceiving the distinction. (See p. 406.)

P prognosis.—In anticipating the issue of a case of lateral curvaturæ, it should be remembered that the flexibility of the spine, in youth, diminishes yearly. Now, as the greater the flexibility, the greater is the proneness of the deformity to get worse if neglected; and as the greater the flexibility, also, the more favourable is the condition of the spine for effecting a cure, it follows that an early commencement of treatment is urgently necessary, both for preventing increase of the curvatures, and for rectifying them. Again, as rigidity of the column increases with years, curvatures of old standing are less likely to become worse than those of recent formation; and, for the same reason, the prospect of success from treatment is more distant in them. Scoliosis, from its earliest to the latest stages, should be regarded as a serious affection; for, although not threatening life, it may be said to jeopardise the future social and physical happiness of the subject.

For testing the stability of the spine, and judging of the efficacy of the treatment, the best mode is, first, to put the patient's body on the stretch by extension and counter-extension; then, to measure the height, both when recumbent and when standing at its fullest, with accuracy; when that has been done, let her lounge at her ease for some time; lastly, let her height be measured after the spine has had time to sink down: the loss observed on comparing the measurements will indicate the mobility of the column.

Treatment.—By reclining in the supine position on an inclined board, the head and armpits being adequately secured to prevent the patient from sliding down, and the lower part of the body left loose, or with some mechanical appliance added to increase the traction, extension and counter-extension may restore the spine, more or less effectually, to its straight position. The benefit anticipated is, that, in course of time, when the vertebræ and connecting structures have been kept sufficiently long in their approximately normal situations, they will become reinstated in them by the influence of growth.

It cannot be doubted that this plan of keeping a patient confined on the back for a long period has proved more efficacious than others. But there are sundry objections to adopting it, especially as an *exclusive* mode of treatment: the chief of these are, the injury to the patient's health, which follows the prolonged confinement; the debility of the muscles that ensues from want of exercise; the comparative seclusion; and the interference with the pursuit of education. Amesbury introduced a useful

FIG. 106. — Extreme Angular Dorsal-cervical Spinal Curvature, from disease and caries of vertebræ (ancliylosis).

couch enabling the patient to combine exercises of the entire body and limbs in the recumbent posture. It has been a constant aim to find a fitting substitute for entire recumbency in spinal supports of various kinds. One of the chief recommendations of these is, that they allow liberty to the patient to walk or sit at pleasure, in common with others; and for that advantage she willingly submits to the irksomeness of wearing them. Whatever ingenuity may be exhibited in the construction—in forming a secure point d'appui at the hips—in introducing contrivances to hoist up the column, or to unbend it—inserting props for strength, or compresses to push the gibbous ribs inward—it is liable to fail; because the mobile human trunk cannot be acted upon as if it were made of insensitive inert material. The remark applies particularly to cases of incipient distortion, when the patients are about fourteen years of age. Later in life, when the vertebræ and ribs are more consolidated, and the pelvis more fully developed, a better purchase can be obtained for the centres of bearing. But when that time has arrived, the curvatures have generally become too stiff and unyielding for treatment of any kind to be serviceable, beyond affording relief to the feeling of weakness and pain.

Physical exercises are essential adjuncts of the treatment. They accomplish various beneficial objects; besides their use in strengthening the muscles, and preserving the health, they have the indirect effect (see p. 427) of increasing the density and solidity of the bones, and adding to the tenacity and power of resistance of the ligaments of the joints. Moreover, they may be made available for stretching the contracted parts in the concavities of the curves; and, by loosening the connections of the vertebræ, they will give greater facility to straightening the column by extension. Excepting in the earliest stage, when the disorder is too often not discovered, it would be vain to suppose that exercises by themselves could effect a cure. They can only be serviceable as auxiliaries.

It appears that, in order to do most justice in the treatment of cases of lateral curvature, the best course is to combine, in various proportions, according to the nature of the deformity, and the age of the patient, parts of the most reliable plans in use, viz.: 1. removal of predisposing and exciting causes; 2. gentle calisthenic and gymnastic exercises; 3. rest on the inclined plain, prone or recumbent; 4. manipulations by a rubber taught to exert particular efforts to reduce the lumbar curvature; 5. the wearing a very simple or more complicated support to head, chest, and spine, as the case may indicate. Experience shows, that when the time of reclining on the plane is broken into at due intervals, by exercises, short of fatigue, indoors and out of doors, the health, instead of being impaired, decidedly improves under the conjoint treatment.

Where a support is needed, the selection of it should not be left to the instrument-maker. Often a very simple support suffices, in which care is taken that there shall be no circular compression of the chest; that the abdomen and loins be well supported, by a firm abdominal band passing behind the back stem of the apparatus, to support, as much as possible, the lumbar vertebræ in front, where they are most disposed to yield. All scoliosis patients exhibit some undue hollowness of loins, and tendency to protrude abdomen. Attention to these points assists the removal of the lordosis. The overlooking of the need of abdominal support to the loins, and directing too exclusive attention to the dorsal distortion, explains many failures in instrumental aids to treatment.

The next point of treatment to be considered is the question of removal of the great weight of the head. This can only be done effectually by recumbency or by suspension, to both of which, through their interference with social intercourse, parents and patients often object. The 'Minerva,' a long known suspension apparatus,¹ has often proved useful.

Suspension of the head by pulleys and weights, whether seated in a chair or in a carriage, or when seated at a piano, has been employed by the orthopædic physician for the last two hundred years. The numerous contrivances for the purpose which

¹ See Little, on *Deformities*, p. 376.

have been published, testify to the general appreciation of the necessity of removing the weight of the head, and the difficulty of effecting it.

The profession has been largely exercised of late by the advertisers of the asserted superiority of plaster-of-Paris,¹ and starch, and white-of-egg bandage, 'poro-plastic,' perforated leather, gutta-percha, or metal corsets. The whole of these contrivances, in the results of their use, often differ little in effect one from the other, or from ordinary whalebone stays. To the artisan, they may be superior as working materials, but they fail almost equally in the important respect that they are apt to press upon the shrunken side as well as upon the protuberant side. They disappoint as to cure, because they do little towards undoing the hidden curves, of which the visible ones afford no proportionate indication. They often satisfy the patient, because they do somewhat lengthen the trunk, afford support, and conceal much of the mischief.

ON CURVATURE OF THE CHEST AND SPINE AFTER PLEURISY.

True or simple lateral curvature.—It is well known that when pleuritic effusion has taken place, the compressed lung is sometimes incapable of expansion, and being tied down by the unyielding fibrous adhesions, remains shrunk, so that the affected side of the chest-wall is drawn towards the contracted lung, is deformed, and appears a permanent and increasing deformity. whilst the unaffected lung and sound side of the chest expands to the fullest normal development, and sometimes beyond it, and appears preternaturally prominent. The collapse and shrinking of one side of the chest involves the vertebral column in the deformity; in short, the chest deformity could not occur without a simultaneous *lateral* curvature of the spine.

FIG. 107.

A represents a drawing from the model taken from a young lady, aged fourteen, who had been affected with pleuritic effusion two years before. The fluid had been spontaneously removed by absorption. It is the simple true lateral curvature of the spine, without the sigmoid twist, which characterises the rotatory lateral curvature of the spine, colloquially, commonly misnamed, ordinary lateral curvature. C represents a drawing taken from a photograph, of the same patient twelve months afterwards. The intermediate treatment consisted of gymnastic exercises, and the use of the lateral sling so as to support the patient upon the prominent side of the chest a few hours daily, by which means the act of chest expansion being mechanically aided on the sound side, expansion of the contracted side is favoured.

The lateral curve consequent upon pleuritic contracture being necessarily concave towards the contracted side of the chest, tends to force the healthy portion of the chest to the opposite side. Viewed in front or behind, there is on the contracted side approximation of the shoulder to the ilium (see fig. 107 A), causing a uniform lateral curve of the spine from the summit of the dorsal region to the bottom of the lumbar one. No other distortion of the spine exists in which a similar simple, continuous, lateral yielding of these regions takes place. It is, in fact, the only true lateral curvature. It has none of the sigmoid character, and no rotation of the vertebrae, which are more

¹ The superiority of plaster of Paris and suspension of the head has been introduced here from America, with beat of drum (as well as the terms *rotary* and *rotato-lateral* curvature) as a new discovery. The use of gypsum as a means of supporting the head, and the use of the terms in question, were probably found in Little, on *Spinal Weakness and Spinal Curvature*, London, 1808, p. 107.

or less marked features of scoliosis, and which induced us to substitute the term rotatory or rotato-lateral curvature for that distortion.

This deformity appears to the casual observer similar to ordinary lateral curvature; and when slight, even the experienced eye may hesitate in diagnosis. When, however, the lateral curvature from pleuritic contraction is investigated side by side with ordinary lateral curvature, although they are in outward appearance similar, no two pathological states can be more dissimilar. The curve after 'recovery' from pleurisy is more uniform, and involves the entire column in one sweep; the depression of shoulder on the contracted side is relatively greater; the reduction of capacity of the contracted side applies to the front as well as to the back of the chest; the posterior angles of the ribs on the expanded side, and the internal margin and inferior angle of the scapula, are less salient (compare fig. 95 and fig. 108); and, as before stated, rotation of the vertebrae on their horizontal axes is entirely absent. It would be interesting to discover whether, in unrelieved cases of pleuritic chest-contraction, after many years' possibly unequal use of the muscles of the two sides of the trunk, any rotatory curve be superadded to the original deformity.

On looking at an ordinary severe scoliosis, as in fig. 103, the observer is there much struck with the bulge of the right side of the chest posteriorly and laterally, and the prominence of the inner margin of the scapula and of the angles of the ribs, and he would emphatically designate this side as the laped and most distorted side.

FIG. 108.

A represents a drawing from a model of the front of a child aged six years, who had been affected with empyema two years and a half before. The matter discharged itself in the usual situation of the 'empyema of necessity,' beneath and posterior to the left nipple. It taken from a model of the back exhibits the deformity as seen from behind in the same child. The absence in these pleuritic contractions or true lateral curvature of the spine of any rotation or twist such as exists in scoliosis (and from which is derived the name) of rotatory lateral usually misnamed lateral, curvature of the spine, is very striking. The case represented in A, and it was an inmate of the London Hospital under our care in 1860. The treatment consisted in lateral slinging during some hours daily, and during the night without the use of spinal support or gymnastics. C and D represent the same case six months later, when the restoration was almost complete. When it is considered that the empyema having discharged itself a fistulous opening had existed for several months, and that consequently the firmest kind of adhesion compatible with the youth of the patient had necessarily taken place, the result will appear surprising to those who still have regard to a considerable pleuritic contraction and deformity of the chest and back as the necessary and unavoidable permanent result of the severest form of pleurisy. It should be remarked that all the models in question were taken whilst the patient remained recumbent, the photographs were taken whilst the patient was standing.

On the contrary, in lateral curvature from recovered pleurisy, the small shrunken side is undeniably the diseased one.

In both kinds of curvature, the enlarged side is more sinned against than sinning; but, in scoliosis or twisted spine, the larger side unmistakably partakes essentially in the entire pathological state, which, in the spine, ribs, muscles, and ligaments, induces the deformity, whilst, in pleuritic curvature, the larger side is essentially the healthy one, and is only physiologically developed to the utmost extent to compensate for the shortcomings of the contracted side.

Auscultation and percussion tend to confirm the diagnosis which the history of the case and ocular inspection and reflection have established.

Posterior curvature of spine (excurvation).—This round-shoulder distortion, like knock-knee, is a frequent consequence of atony, rickets and of old age. It can be distinguished from angular distortion, by the curve of the spine being a gradual one, no single spinous process being prominent in so marked a degree as in angular deformity by the existence of signs of rickets elsewhere, by the absence of the history of vertebral disease, which precedes angular deformity, and by its rarely reaching so great deformity as the angular form. A frequent exciting cause is the injudicious

permission of late hours in relation to age, the undue proportion of time devoted to sedentary pursuits. Where no rachitic element is discoverable, debility, from overgrowth, may have been the remote cause.

In the early stage this antero-posterior yielding of the vertebræ disappears when the subject is recumbent; but in the advanced stage the muscles situated in the concavities of the curves, as well as the articular surfaces, having adapted themselves to the altered relation of the parts, the change from the perpendicular to the recumbent posture effects no variation in the deformity of the dorsal region and seldom in the lumbar region, unless the thighs be flexed; by which means the *proæ* muscles being relaxed, the lumbar vertebræ sink towards the couch. Even this temporary alleviation of the deformity, with the lapse of time, disappears. The injurious effect upon the thorax is less considerable than that resulting from other spinal deformities. The treatment consists in obviating the constitutional rachitic state, when still present; in removal of the exciting causes enumerated; and by a judicious system of moderate gymnastic exercises and youthful strengthening games. The posterior curvature in the upper part of the spine is accompanied with a compensatory curve in the dorso-lumbar region termed *lordosis*, *anterior curvature*, or *incurvation*.

The causes and treatment of the upper or posterior curvature apply equally to the lower or anterior curvature. A light spinal support, the action of which should tend to make a fulcrum of the most prominent part of the dorsal region, obtaining a leverage upon the shoulders by means of straps passing around them, is useful. This tends to reduce the upper curvature, whilst the lower part of the support, being buckled around the pelvis, will, by means of a broad strap acting on the front of the abdomen, tend to reduce the anterior curve. But, as physical exercises in the shape of the use of dumb-bells, clubs, the trapeze, and ordinary boy's out-door games are desirable, the support must be removed for such exercises at stated periods. If the lumbar hollow be very considerable in an advanced adolescent, the distortion may never be completely remedied. The most unpromising cases of lordosis, however, often yield to perseverance in physiologically directed special exercises.

LORDOSIS.

From paralysis from hip contraction and luxation, congenital and acquired, and from excessive use.

Undue hollowness of loins is an ordinary prominent symptom of the above forms of disease. It is irremediable when the cause continues to operate. That which springs from excessive use, as in the acrobat, is due to the individual having, from forced continued exercise of the part, in special exercises during early life, gradually elongated the lumbar ligaments and the minor muscles, and so changed the articulating surfaces of the vertebræ that unphysiological postures become possible even into later life. Changes corresponding to these, doubtless, occur in other parts of the frame, as in the neck, head, and ligaments of the thigh-bone, &c.

Congenital hip luxation.—A strongly marked condition of lordosis may lead the practitioner astray as to diagnosis, if he be not made aware that it constitutes a marked symptom in a very different and more serious affection, viz. congenital hip luxation, especially when this is double. In this cause of lameness and impairment of the figure and strength of the individual, the powerful normal connection of the pelvis and trunk with the lower extremities is much abated, or even lost, owing to the heads of both femurs not occupying their natural position in the acetabulum, or from the ill-developed acetabulum occupying a site in correspondence with the displaced head of the femurs. In addition to displacement of position, all the bony parts concerned are small and wasted. The consequence is, as it were, that the pelvis, and with it the trunk, sink down between the thighs, the pelvis inclines unduly forwards, whilst, in order to recover his equilibrium, the individual throws the upper part of the trunk backward, thus engendering the remarkable hollowing and shortening of the loins—the lordosis. This is not the place to dwell upon the means proposed for the relief of congenital hip luxation. It is sufficient to say that the

attempts to effect a radical cure by operation have constituted, to say the least, a weakness on the part of surgeons practising orthopedic surgery.¹ They have all, as far as it is known, proved untrustworthy, which could not be otherwise, through their having been based upon hypothetical expectations and hopes rather than upon sound pathological experience. As to successful treatment, it must be confined to the attempt to delay and arrest, during the years of growth, the gradual degradation of the head and neck of the femur, which takes place more or less rapidly according to the amount of exercise taken, by advising the parent to prevent the patient taking any considerable walking exercise that can be avoided, or the use of sticks or hand-crutches, and recommending daily airings on the water or in land carriages. When the surgeon can by manipulation replace the head of the femur in the socket, it mostly slips out again immediately. We have commonly prescribed a tolerably tight india-rubber bandage, or a webbing strap and buckle to be worn around the hips, to attempt to limit the tendency of the bone to further displacement. We have seen this congenital luxation hereditary, although it is said sometimes to result from accident, or from art interference during parturition. When such is the origin, the luxation probably is single.

Paralytic spinal curvature.—We have (p. 443) alluded to the influence of paralysis in the production of one form of lordosis, which is an instance of the operation of unequal or impaired muscular power, producing spinal curvature. Many years ago we published illustrations² of severe helpless paralytic spinal curvature which were exceptional cases, and mainly interesting to the pathologist by showing how great malformation may result from this cause. These were cases resulting from severe disease of medulla spinalis in childhood (progressive muscular atrophy and others). We also gave an illustration³ of spinal curvature from hemiplegia in childhood. Considerable spasmio-paralytic scoliosis, as stated in this work (p. 247), may arise from the effects of asphyxia neonatorum. Dr. Louis F. Stromeyer in the outset of his career attributed ordinary scoliosis to paralysis of the inspiratory muscles,⁴ a view to which we have been unable to subscribe. Dr. Schaffer,⁵ in a recent able lecture, speaks of a paralysis in scoliosis, which is not in our opinion a correct use of the term paralysis, because he simply refers to the weakness and wasting of muscle following disuse. We have said sufficient to show that paralysis is a very exceptional element in spinal curvature.

*Active spasmodic and hysterical scoliosis.*⁶—We have met with several cases of well-marked considerable scoliotic distortion of spine, due to active morbid muscular action. Two of these were in-patients of the London Hospital. All were in young females between the ages of ten and twenty years. In more than one, circumstances were observed in the demeanour which left no doubt of the hysterical character of the disorder; one was more than twelve months under observation, and underwent no fluctuation in degree, or positive amelioration. The curvature of the column to the left in the dorsal region was so considerable as to excite surprise that the anatomical conformation of the spine could permit so considerable a deviation with hysterical suddenness; for occasionally, on distracting the patient's attention, the spine became quite straight. One of the hospital cases was a precocious girl of thirteen, probably of hysterical temperament: the distortion was distinctly spasmodic, and no volitional influence in the production of it was discoverable. After spending ten days in bed, subjected to the regulations in force, applicable to all patients supposed to be ill enough

¹ Whilst these leaves were in the hands of the Editor, we read in Farnach (*Bericht der Königl. Chirurg. Klinik, Kiel, 1880*) a case of 'Luxat. Coxæ Cong. (Weib) *geheilt nach mehrmonatlicher Behandlung mit Streckverbanden.* Der Fall wird demnächst publicirt.' Has the benefit proved to be permanent?

⁴ L. F. Stromeyer, *Ueber Paralyse der Inspirations-Muskeln*, Hanover, 1892.

⁵ *The New York Medical Gazette*, April 1881, p. 125.

⁶ We prefer these terms to 'simulated' (Jules Guérin) or 'mimetic' (Paget), because we are satisfied that very often the subjects have probably never seen a case of similar deformity. By the use of the term hysterical we absolve the individual from the charge of attempting to deceive.

to require confinement, she requested permission to dress and walk about the ward. This being refused on account 'of the severity of her case,' the spasmodic affection subsided after the lapse of a few days more, when she was handed over, 'cured,' to her friends, with suitable injunctions as to her future management. Such cases, with tonic diet, and rest, with the favourable social and moral influences of a well-regulated hospital, upon such forms of nervous disorder, usually do well quickly. In private life, the surroundings of such cases are sometimes anything but favourable.

In none of these cases did secondary changes in the form of ribs exist. The neurotic character did not affect the nutrition and development of parts, after the manner of ordinary scoliosis.

Hysterical or emotional spinal curvature sometimes assumes the form of angular curvature in the lumbar region, the spinous process of the 1st lumbar, in fast-growing tall girls, standing out sufficiently to induce parents and medical practitioners to seek an additional opinion. We have seen several of these instances, in which the spine prominence was very marked, and much resembled that of angular *disease*, but all other signs of disease were absent. The history of these cases has usually been the following: at the expected menstrual period, the individual has been asked whether she had pains in the back; the back has been examined, and a prominent point discovered by the too anxious parent, who was ignorant that the last dorsal or the 1st lumbar vertebra is apt to increase in size, be prominent, and complete its growth, about the time that the pelvis rapidly enlarges. In girls who do not carry themselves fairly upright, the physiological growth is mistaken for a morbid state. The statements and reflections thereon are heard by the girl, her mind yields to the prevailing impression as to existing disease. With tact the physician can always show that the prominence is a removable one, under the influence of the patient's volition, which cannot be done when *disease* exists. By the physician admitting the patient into his confidence, that there is no incurable disorder, and that it will soon get well, and with prudence on the part of the living environment, the cure is effected.

W. J. LITTLE.

SURGICAL DISEASES CONNECTED WITH THE TEETH, AND THEIR TREATMENT.¹

THE limited space allotted to this essay compels me to forego, to a great extent, dwelling on those diseases which most commonly fall under the special care of the dentist, and to confine myself, almost entirely, to those surgical *complications* which are associated with, and dependent upon, abnormal conditions of the teeth.

The subject of 'teething,' and the ailments of childhood contingent on that process; the irregularities and deformities depending on the shedding of the temporary teeth, and the advent of their permanent successors, would alone occupy, if treated with justice to their importance, more space than could be afforded to the entire essay.

Another matter which is of the last importance in the treatment of the teeth, *stopping* or *plugging* carious cavities and other defects of the surface, is a subject of such extent, and involves so much preliminary discussion upon purely physical questions, that it is impossible to enter here upon its consideration. Indeed, the treatment of those most usual and ordinary abnormalities of the teeth, irregularities of the position of the permanent set in young people, and carious cavities, entail to so great an extent a particular mechanical knowledge in combination with surgery, both its science and art, that it has naturally, and indeed inevitably, assumed that *special* character of practice and of surgical treatment which we see at present accorded to it: and for these reasons, combined with the want of space which I have before mentioned, I am constrained to refer the reader, for the consideration of these subjects, to those works which have been specially devoted to their elucidation.

In the following pages, therefore, I shall describe, as far as my limits allow, those surgical diseases and abnormalities, with their treatment, which are more or less connected with the teeth, under the following heads:

- I. Alveolar abscess.
- II. Painful and difficult eruption of the wisdom-teeth.
- III. Tumours of the gum.
 - (a) Epulis.
 - (b) Congenital hypertrophy of the gum and alveolar borders of the maxilla.
 - (c) Polypus of the gum.
 - (d) Vascular tumours.
 - (e) Warty tumours of the gum.
- IV. Tumours of the tooth-pulp.
 - (a) Polypus of the tooth pulp.
 - (b) Sensitive growth of pulp after fracture.
- V. Odontomes, or tumours of the hard tissues of the teeth.
 - (a) Enamel nodules.
 - (b) Exostosis.
 - (c) Hypertrophied fangs.
 - (d) Dentine excrescence.
 - (e) Warty teeth.
- VI. 'Abscess' of the antrum.
- VII. Dentigerous cysts.

¹ The author is indebted to Mr. Coleman for much kind assistance in revising the present edition of this article.

VIII. Alveolar and maxillary necrosis from

(a) Phosphorus fumes.

(b) Eruptive fevers.

IX. Hæmorrhage after extraction.

X. The application of obturators and artificial palates.

I. *Alveolar abscess*.—One of the commonest consequences of dental caries, and occurring occasionally independent of any apparent disease in the teeth, is this troublesome, and too often ill-understood, malady. The results of this condition, when appearing on the external surface of the face (cheek, jaw, or chin), are occasionally so remote from any obvious connection with the teeth, and the patient's symptoms so fail to indicate its association with them, that the true nature and cause of the suppuration is lost sight of, and an easily-remedied disease is indefinitely protracted.

Alveolar abscess may be defined as a suppuration around the fang or fangs of a tooth, usually carious, accompanied by absorption and expansion of the bony walls of the alveolus or alveoli, and the enlargement of the little pus-sac, the matter gradually finding its way to the surface either along a canal by the side of the fang of the tooth opening at the edge of the gum, or through the gum itself at a point corresponding to the end of the root (or roots) of the tooth implicated. When, however, the fangs are unusually long, or the reflection of the mucous membrane, from the gum to the cheek or lip, is very superficial, this same discharge may burrow still more outwardly, and find its exit upon the surface of the face.

The pathology of alveolar abscess, especially in its commonest form of 'gun-boil,' was long misunderstood. The first change which occurs in the development of this condition consists in the deposit around the extremity of the fang or fangs of the tooth of organised lymph, which is soon differentiated into obscure fibrous tissue. Coincident with this development, the bone around the end of the tooth-fang becomes absorbed, and a little hollow in the jaw is produced, varying in size from a lentil-seed to that of a horse bean. Thus far the change is simply one of plastic inflammation: it occurs, as far as my observations go, with every carious tooth, and in those with more than one fang is most conspicuous at the extremity of that root which corresponds with the side or part of the crown where the caries occurs.

These changes are often accompanied by absorption, to a varying amount, of the extremity of the fang; and this appears to be part of the same action as produces the excavation in the maxilla itself, which is occupied by the plastic exudation. There is generally, too, a thickening of the alveolar periosteum, which raises, and often loosens, the affected tooth.

It is the lymph surrounding the extremity of the fang, and occupying the little cavity produced by the bone-absorption, that is the seat of suppuration in alveolar abscess. Whatever may be the first actual point of suppuration, when sufficient pus is formed for recognition, it is found in immediate contact with the fang of the tooth—the bare, naked crusta petrosa, and surrounded by the half-organised lymph, as by a sac. The form of this sac varies considerably; it is usually spherical or pyriform where the fang is single, or if the tooth have more than one fang, and the fangs are distinct; but where the fangs are close together, or the root is simply cleft at its extremity, as is often the case with the superior premolars, the sac is frequently double and bilocular. The sac is sometimes of large size, and is frequently very long; sometimes it is fringed with finbriated processes of lymph, which occupy an elongated excavation in the maxilla. When suppuration is established, the sac enlarges according to the amount of matter formed, and the rapidity with which it is developed; and this is accompanied with a dilatation and absorption of the bony walls of the abscess, especially towards the region at which the matter is 'pointing.' These latter changes are often very extensive and very rapid; so that the whole of the osseous tissue of one wall of the alveolus may be expanded and thinned into a more papery film, and then completely absorbed in comparatively few hours, the periosteum, with the organised lymph that has been the seat of the suppuration, alone remaining as the membranous sac of the abscess. The development of an alveolar

abscess is generally accompanied by a deep throbbing pain at the part affected, and often by great general swelling of the face, sympathetic of the more internal mischief. The distortion of the countenance from this cause is sometimes prodigious, especially when the upper incisors or canines are the cause of the abscess, and the attack is acute. In such a case the nose will be pushed on one side, the eyelids become œdematous, closed, and ecchymosed. In other instances, where the character of the affection is less intense, a mere indurated, indolent, and hard swelling on the side of the jaw is all that is produced; the maxilla being distended at the extremity of the tooth's fang, and but little bone absorbed.

The development of an alveolar abscess is sometimes associated with febrile symptoms of extreme severity. M. Robert¹ describes a case of alveolar abscess, resulting from a carious wisdom-tooth, which led to necrosis of the surrounding bone, and diffuse purulent infiltration of the side of the neck. The case terminated fatally.

Alveolar abscess is usually confined to the tooth or one fang (when the tooth has more than one) which has been the cause of the affection, and around which the plastic exudation has formed. Occasionally, in two- or three-fanged teeth, the intervening bone between the extremities of the individual fangs becomes absorbed, and one abscess may be common to all. Again, there is another form of alveolar abscess which occasionally affects the upper jaw and front teeth in persons of cachectic and debilitated constitution, in which suppuration appears to affect generally the tissues surrounding the roots of several teeth in a diffuse manner: the teeth become excessively loose, and the front of the jaw around them becomes boggy and suppurates abundantly, the discharge usually flowing around the necks of the teeth. In such cases the teeth are often, indeed generally, sound, and are probably only secondarily affected. I incline to the opinion that this form of alveolar abscess is dependent on constitutional taint—scrofulous or syphilitic.

The 'pointing' of the matter in alveolar abscess is a question of some moment, both as regards diagnosis and treatment; and the circumstance that the discharge of pus may occur upon the surface of the face, entailing it with very great disfigurement, adds serious importance to this consideration.

An alveolar abscess affecting the one-fanged teeth may find vent for its secretion by a gutter or channel along the course of the fang, the matter being discharged at the neck of the tooth. This seldom occurs to the many fanged teeth, and is most commonly seen with the inferior incisors—the pus flowing from the front edge of the gum at a point corresponding with the particular tooth affected. The commonest position at which the thinning and bursting of the abscess takes place is on the outer surface of the jaw, at a point corresponding, as nearly horizontally as may be, with the extremity of the fang of the affected tooth, and *piercing the gum within the mouth*. In such common cases the diagnosis is perfectly simple and obvious, and the abscess is easily associated with the individual tooth that produces it. There are, however, instances in which the pointing of the abscess, after having taken a lengthened and burrowing course, is remote from its cause. The most striking peculiarity of this kind is where a circumscribed collection of matter appears far back in the palate, occasionally at the very posterior extremity of the hard palate, dependent on affection of one of the six front upper teeth. Such a condition may readily fail to indicate its true explanation, and may suggest the presence of necrosed palatal bone; it is important, therefore, in the practice of general surgery, to recollect that this obscurity may present itself. As far as my own experience has gone, caries of the *superior lateral incisor* tooth has generally been the cause of this remote pointing abscess. Why it should be so, I cannot say; but the pathological anatomy of the affection is the same as in ordinary cases, only the canal of the abscess is lengthened out in the narrow cancellated bone between the two compact plates of the palatal process of the superior maxilla. A critical scrutiny of the front teeth (incisors and canine) will scarcely fail to show which is the offender.

¹ *Conférences de Clinique chirurgicale*, par M. A. C. Robert, p. 145. Paris, 1860.

The forms of alveolar abscess which we have just considered are trivial in their importance in comparison with those which, in their advancing course, involve the integument of the face. It is a curious circumstance that alveolar abscesses, when pointing externally upon the face, have been so frequently misunderstood by surgeons, having been mistaken either for idiopathic abscess in the substance of the cheek, or suppuration associated with necrosis of more or less of the maxillary bones. To the superficial observer (and, indeed, in its consequences) there is a vast difference between a common gum-boil and an abscess which pierces and discharges its contents upon the surface of the cheek; but the cases are the same, barring the point where the pus is evacuated.

The circumstances which determine the pointing of an abscess upon the surface of the face appear to be either an unusual length of the fang of the tooth, or a superficial reflection of the mucous membrane from the jaw to the cheek; so that, in either case, the abscess which is forming round the extremity of the fang does not correspond horizontally with the gum within the mouth, and thus in its course outwards it passes either above or below (as it may occur in the upper or lower jaw) the line where the mucous membrane folds from one surface to another. In some cases, however, it takes an outward form irrespective of these conditions.

I am not aware that alveolar abscess, associated with the superior incisors or canines, ever points upon the surface of the face; the bicuspid, first and second molar, and all the teeth of the lower jaw, may produce this form of the disease. In the upper jaw the abscess appears upon the cheek at a point corresponding with the extremity of the tooth's fang, under the edge of the malar bone; in the lower jaw it forms along the edge of the jaw below the buccinator muscle when the molars or bicuspid are its cause; but when associated with the inferior incisors (canines also), it points frequently beneath, and sometimes in front of, the chin.

When an alveolar abscess is about to point externally, the integument becomes firmly glued down to the bone around the spot where the matter ultimately appears; the area within this space is red, distended, and glistening; the skin becomes thin and papery, and the epidermis scales off. If the surface be kept dry, the breaking of the abscess is often tardy and delayed; but it ultimately bursts through a jagged opening, which soon changes into a small fistulous orifice, surrounded by a pouting circular lip of granulations, that sink into a depression, surrounded by the adhesions which limit the pus-discharging canal. The appearances now are very characteristic, and when once recognised cannot be afterwards mistaken. Sometimes the lip of granulations becomes elongated into a papilla, and is covered with cuticle. I have seen one more than half an inch in length. The apex of this papilla has an orifice, which is the outlet of the fistulous canal communicating with the abscess; it frequently closes for a time, but bursts again as the matter accumulates. When once this papilla forms, it returns again and again, after excision by the knife, till the cause of the whole malady (the carious tooth) is removed. Another curious modification of the external orifice of the alveolar abscess is occasionally seen when it pierces the under surface of the chin; in such a case a *pad* of granulations sometimes forms, as large as the area of one's thumb-nail, from the centre of which the discharge flows.

In children, with the milk-teeth, alveolar abscess very seldom opens on the surface of the face. I have, however, seen a few such cases. On account of the extreme thickness of the alveoli in them, the end of the affected fang frequently appears through the orifice of the discharge within the mouth, and often projects so far as to wound and ulcerate the mucous membrane of the cheek or lip.

It sometimes happens, that after the first evacuation of the pus of an alveolar abscess the secretion becomes serous. I have known some instances in which the sac of the abscess has remained as a serous cyst even after the extraction of the tooth upon which it originally depended, the secretion recurring again and again after the cyst had been lanced. In one instance, where it had happened in a child in connection with an upper incisor tooth, I found it necessary to remove a portion of the wall of the cyst, when it granulated from the interior, and was obliterated.

The *diagnosis* of alveolar abscess is really very simple, though, as I have said, it is often mistaken for diseased bone in those examples where the orifice occurs on the surface of the face. The tooth is the equivalent in these cases of a sequestrum; and it is, as far as the pulp-vitality goes, a dead organ. The fistulous canal leads to the dead tooth, as a sinus to the dead bone; thus far the two conditions are alike, and their appearances are alike; but there are obvious differences. In alveolar abscess there is general swelling, except at first in acute cases, and there is an absence of the diffuse indurated lymph-infiltration of the cellular tissue which is present in bone-necrosis; the canal leading to the abscess is single, usually short and direct, and not burrowing and complicated as in bone-disease;¹ moreover, there is generally an absence of fetor in the discharge. The locality in a doubtful case, being the neighbourhood of the jaw, is in favour of the idea of a tooth being the cause; and an appeal to the state of the teeth seldom fails to settle the question definitely. Sometimes, however, a difficulty may arise from the fact that the cause of the abscess is a mere stump, overlapped by prominent gum; or, what occasions still more obscurity, the abscess may consist of a large excavated cavity in the substance of the jaw, into which the stump has fallen and become loose and free; or it may depend on an impacted tooth. A probe and the elevator will in either case complete the investigation.

While alveolar abscess, when connected with the integument of the face, is very apt to be mistaken by surgeons for diseased bone, the reverse has happened where a dentist has attributed to carious teeth morbid conditions which have been coincident with them, though not produced by them. I have known this occur in an instance where the patient was suffering from scrofulous caries of the malar bone near its suture with the superior maxilla—a mistake which led to the extraction of two slightly damaged teeth in no way connected with the disease. Again, I have seen one of the sub-maxillary lymphatic glands, rather adherent to the bone and in an early state of suppuration, mistaken for an outward-pointing alveolar abscess. Such errors as these, leading at most to the extraction of carious, though innocent, teeth, are trivial in comparison with those more frequent mistakes in which alveolar abscess is confounded with bone-disease, and an easily cured malady is allowed to run its course unrestrained, and permanently disfigure the face.

The *cause* of alveolar abscess is either caries of a tooth or death of the organ; the latter usually the result of mechanical violence, which has separated the pulp from its continuity with the subjacent nervous and vascular structures. It is uncommon to see the affection arise in association with sound and apparently uninjured teeth, though this sometimes occurs.

The *treatment* of alveolar abscess depends upon the stage at which the case is seen. In the earliest period, when suppuration is rather impending than established, the malady may be cut short by the extraction of the offending tooth, or by the removal of the stopping in a stopped tooth. Often it is undesirable to extract a particular tooth that may be threatening or causing the abscess; and in that case recourse should be had to leeching the gum freely, the administration of brisk purgatives, and abundant hot fomentation of the mouth. This mode of treatment, when it does not arrest the malady, much mitigates the attendant suffering. When matter has formed, and the wall of the abscess has sufficiently thinned, the pus should be evacuated by a puncture made through the gum with a narrow thin scalpel. This is followed by immediate and complete relief, and the general swelling associated with the advent of the attack rapidly subsides; but the disease, in the very great majority of cases, remains in the form of a continuously pus-discharging fistula. It is very rare indeed

¹ I once saw a very remarkable exception to the above, nearly universal, rule. A lady consulted me on account of a burrowing abscess, which first burst immediately below the lower jaw on the right side. This orifice closed and another formed lower down: this also closed, and was followed by another in the neck. The burrowing continued, and when I saw the patient, many months after the first discharge of pus, there were two sinuses opening about an inch below the right clavicle. A carious first lower molar had caused the suppuration, and its removal was followed by the immediate healing of the sinuses.

for the pus-secretion to cease : it may be so diminished that the external orifice may close for a time, but it is pretty sure to burst out again and again ; though I am confident (contrary to the general published opinion) that in a few exceptional instances the disease ceases altogether, the offending tooth still remaining in the mouth.

When an alveolar abscess shows symptoms indicative of external pointing, immediate and active treatment is necessary. The offending tooth should be taken out ; and in case it breaks in extracting, every vestige should be sought and removed. If matter has formed, and there has been decided thinning of the integument, showing its near approach to the surface, not only should the tooth be extracted, but a vertical incision should be made between the cheek and the jaw, so as to cut across the pus-containing canal ; else the matter is apt to *pocket*, and cause progressive absorption to the surface ; and though the tooth be removed, the abscess may thus still open externally. This vertical incision between the cheek and the jaw is also useful after the removal of a tooth, even when the external opening has occurred ; it cuts across the bands of lymph which glue the integument down to the bone : in this case a piece of oiled lint should be introduced and kept in the wound, to prevent the adhesion and reunion of the cut surfaces. In all cases of alveolar abscess, extraction of the diseased or dead tooth is the cure ; and I know but of two circumstances which peremptorily interdict this mode of treatment. First, where a strongly-pronounced hæmorrhagic diathesis forbids the extraction of teeth altogether ; and secondly, in those cases where the abscess is associated with the upper incisor teeth of young people in whom the jaws have not yet assumed their adult form, and where the permanent dentition is, as yet, incomplete. In this latter case it is of much importance to retain the teeth, even if reduced by decay to mere fangs, till the adult form of the jaws is established, even at great cost of suffering and discomfort. The earlier removal of the teeth would be followed by such contraction of the maxillary arch as would be incompatible with a proper replacement by artificial teeth of the natural ones missing.

II. *Painful and difficult eruption of wisdom-teeth.*—The advent of the wisdom-teeth is very often accompanied by painful and distressing symptoms, that may be protracted through many months, or even years, unless relieved by surgical interference. These circumstances arise from the position occupied by the wisdom-teeth, so close to the joint of the lower jaw, where the mucous membrane is reflected from the gum to the cheek and fauces, combined with the very common condition—that the jaw is not sufficiently elongated backwards to allow the *dentés sapientiæ* to range in the horizontal series with the other teeth. This mechanical difficulty not only prevents the proper evolution of the wisdom-teeth, holding them back in their bony bed, but it often perverts their direction of growth and dislocates them. Annoying and very painful as are often the symptoms attendant on difficult cutting and misplacement of the upper wisdom-teeth, they are trivial in comparison with those which occur in similar conditions of the lower.

The ordinary misplacement of the upper wise teeth is either backwards or outwards, or in both directions combined. When the tooth points backwards, every time the mouth is closed its crown comes in contact with the mucous membrane, passing up on the base of the coronoid process ; when the direction is outwards, which is more common, the tooth projects into the cheek, and when the jaws are brought together, a portion of the mucous membrane in this region is nipped and pinched. This is a very painful affair : the surface becomes ulcerated and extremely tender ; there is a partial cicatrisation, and the structure becomes stiff and hard as well as painful. Beyond this, however, the symptoms never (as I believe) extend, and the removal of the offending tooth is always followed by complete and immediate relief.

The difficulty which most commonly occurs with the inferior *dens sapientiæ* is attributable to insufficient room in the jaw : the tooth grows normally in direction and in position as regards its neighbour in front, but, from an imperfect lengthening of the horizontal ramus of the jaw, the birth of the crown is only partial and incomplete : the tooth is upright, but only its front cusps emerge, while the hinder cusps

are still covered in with gum, or even the upper wall of the bony locus in which it was formed. This produces a terrible pinching of the mucous membrane over the tooth every time the jaws are brought together. Before, however, the enamel eminences of the tooth's crown make their appearance, the soft structures behind the second molar become much inflamed, and often suppurate, the pus-secretion appearing to be within the enamel sac of the tooth, between the tooth-crown and the membrane covering it. The inflammation, to which this impaction and pressure give rise, extends to surrounding tissues: the cheek and fauces suffer; the movements of the jaw become stiff and painful; and deglutition is difficult, and attended with suffering like 'sore-throat.'

Next in frequency to the foregoing malposition is that in which the wisdom-tooth is developed horizontally forwards, more or less. It is attended often with serious consequences. This direction is sometimes combined with an inward leaning; and very rarely the crown of the tooth points outwards. This latter dislocation is very unusual; but the most severe case of suffering from misplacement of the lower wisdom-tooth which I have ever seen was of this variety.

There is one peculiar symptom frequently associated with the painful cutting of a lower wisdom-tooth, which adds to the difficulty of investigating the condition of the parts, and still more interferes with the treatment: this symptom is *spasmodic contraction of the masseter muscle*, of a continuous and persistent character, the result of contiguous irritation; not a spasm which varies in intensity, but a true *tonic* spasm, the muscles being permanently *set*, so as to keep the jaws nearly closed, and susceptible only of very slight separation. The jaw can usually be opened to a small extent, and then is definitely fixed; it feels as if there were a mechanical obstacle to further movement; but it is not so; for when the cause of irritation is removed, the spasm rapidly ceases, and then the mouth can be fully opened. This same form of spasm sometimes occurs from caries of the molars, irrespective of crowding. The pain that accompanies and precedes the cutting of a wisdom-tooth varies very much in different individuals; but it is frequently of a dull aching character, like rheumatism, for which it is occasionally mistaken; it is diffuse and erratic, extending up the side of the head, and down to the shoulder. There is not unfrequently a good deal of swelling of the soft parts in the neighbourhood of the tooth, and this sometimes extends to the cheek and to the eyelids even, and below the angle of the jaw: the lymphatic glands beneath the jaw also occasionally become enlarged and tender.

The most distressing result, however, that occurs in these cases is the suppuration which sometimes attends the difficult eruption of the tooth. In slight cases, even where there is no misplacement or want of room, but simply a restrained progress, from an unusually dense or cartilaginous overlying gum, pus will be occasionally formed; being secreted (as it has seemed to me) within the capsule of the tooth, by that which was the 'enamel pulp.' In severer cases, the pus burrows among the areolar tissue, around the periosteum of the jaw; the neighbouring soft structures become infiltrated with lymph, and the integument is glued irregularly to the bone; pus points at different spots, often remote from its original source; and the whole cheek may be undermined with a series of sinuses. I have seen the side of the face, from the tragus of the ear and the angle of the jaw behind, to the angle of the mouth and mental foramen in front, a web of pus-discharging fistulae, and which, after their cure (by the mere removal of an impacted wisdom-tooth), left the integument thin, and bound down to the bone, with the glossy, tense, cicatrix-like aspect of a recently-healed burn—a great and permanent disfigurement. While such cases are in activity, they have very much the appearance of necrosed bone. And, indeed, they do occasionally lead to necrosis of more or less of the jaw; but the severest suffering and most suspicious symptoms may occur without such a complication. What is the precise anatomical condition of these burrowing suppurations I am not prepared to say positively. They are not apparently connected with the fang of the wisdom-tooth, like an alveolar abscess. I believe they commence in the enamel sac, before any portion of the crown pierces the gum; and their subsequent course of burrowing is from the matter *pocketing* in a downward and onward progress. As long as any

part of the crown of the tooth is covered by gum, pus will be secreted by the under surface of the overlying portion. I have seen an impacted wisdom-tooth give rise to that form of serous cyst known as a 'dentigerous cyst.' In those instances where the crown of the wisdom-tooth projects forwards, the second molar very often suffers. The posterior fang is apt to be eroded by absorption, and the whole tooth may become necrosed; the first of these conditions is very common: I have met with several instances of it; in four specimens of lower second molars now before me, which were removed on account of forward pressure of wisdom-teeth, the posterior fangs are excavated by absorption in all; in two the pulp cavity is closely approached; in two it is opened, and in one of the latter there was total necrosis of the whole tooth; the periosteum was completely stripped from both fangs, which were unattached in their sockets, and bathed in pus. These affections of the second molar should be taken into consideration in balancing the merits of the plans of treatment which may be contemplated in any particular case, and will, I think, favour that course of proceeding which I believe ought in many instances to be followed, but which is not now usually adopted.

Treatment.—The wisdom-tooth of the upper jaw, when misplaced, suggests but one mode of treatment; it by far the most often projects outwards; it is then useless for mastication; and if it pinches the cheek painfully on closing the mouth, it may be removed unhesitatingly and without compunction. The same may be said when it grows backwards and bruises the mucous membrane over the base of the coronoid process; the tooth is useless, and worse than useless, and should be extracted; it is very readily done, and, as far as I know, the annoyances attendant on the misplacement of the upper wisdom-teeth are never attended with that locked-jaw complication which so frequently attends the difficulties of the lower third molar eruption. In one rare instance, in which the upper wisdom-tooth grew forwards, it was found necessary to extract the second molar, on account of damage which it had occasioned by producing absorption of the neck of the anterior tooth.

In the treatment of these cases in the lower jaw, much will depend on the degree of impaction of the tooth; if it is simply covered over by a dense and cartilaginous gum, free lancing is all that may be required; but it will often have to be repeated. In young precocious people, who arrive very early at puberty, the wisdom-teeth often make their appearance before the jaw is ready for their reception, and are imbedded in the base of the coronoid process, though in a proper upright position. The age of the patient in such a condition is an important question; if young, lancing the gum freely, and waiting for further elongation of the jaw, and more horizontal accommodation, may be fairly and reasonably adopted: but the same state of things in an older patient is not so likely to find this relief; and if the suffering of the patient is great, extraction of the impacted tooth will become necessary. Where the tooth emerges tardily, and where the anterior cusps have come through the gum while the posterior have remained covered, I have found great advantage not only in lancing, but in cutting away the gum which overlies the back of the tooth, so as to lay bare the whole of the masticating surface of the crown. Merely lancing the gum affords much less relief, and the cut surfaces are apt to unite, and then present a harder and more resisting impediment. If the impaction is severe, and there is no chance, from the age of the patient, of sufficient accommodation, it will be necessary to extract a tooth, so as to relieve the crushing tension; and the question now arises as to which of the two, the second or third molar, should be extracted. *Cæteris paribus*, it is always better to sacrifice the third than the second molar: the wisdom-tooth is less useful for mastication, and is more liable to decay; it is altogether less robust: but the circumstances of the two teeth may not be equal or parallel—the second molar may be carious, or it may be loose or necrosed by the pressure of the tooth behind it: in either case I prefer extracting it to the wisdom-tooth. Again, the wisdom-tooth may be so situated that its extraction may be a physical impossibility, or nearly so, as is frequently the case where it grows horizontally forwards, deep down in the jaw. Another reason, the rigidity of the masseter spasm, may render it impossible to reach the tooth. In either case I should extract the second molar, though

perfectly sound, without hesitation. The distressing symptoms which are peculiar to the difficult eruption of the *lower* wisdom-tooth—the heavy pain, the sense of *tension* and *pressure*—are clearly dependent on the antagonism of the third and second molars; the former pushing forward into place, and the latter resisting its progress. The removal of the second molar puts an end to this antagonism as completely as that of the wisdom-tooth; and, in result, the one operation gives as entire and immediate relief as the other. When the second molar is extracted, the wisdom-tooth comes forward wonderfully; and an oblique or nearly horizontal tooth will advance in position, and alter in attitude, so as to become nearly, or quite, vertical, and a fair opponent to the upper second molar. In this improved position, when it can be used habitually in mastication, the *dens sapientiar* is less liable to caries. But when suppuration has become established, every effort should be made to remove the wisdom-tooth itself, as the extraction of the second molar, under these circumstances, generally fails to arrest the discharge of pus.

The closure of the jaws is often so complete that, until this condition has been combated, it is impossible to get at either of the molar teeth. By pressing apart the jaws with some sort of wedge, this may be accomplished gradually, and in two or three days sufficiently to allow the removal of the tooth selected for extraction. Steel instruments have been devised on the principle of an ear speculum, composed of two shafts or blades, which separate slowly, but forcibly, by the action of a screw. I prefer a wedge of hard wood, such as beech or box-wood, which is pushed further and further into the mouth, as the contracted masseter yields before it. It seems to obliterate the spasmodic contraction for so much at each further introduction, and in a few days such an instrument will open the mouth sufficiently for tooth-extraction. Another arrangement, however, invented by Mr. Maunder, of the London Hospital, seems to possess advantages over those previously in use. It consists of a cone of box-wood or ivory, upon which is cut a spiral screw-worm, gradually increasing in diameter and in thickness of the worm; it resembles the shell of a univalve mollusc, such as a whelk-shell, only the spire is more elongated and drawn out. In cases where closure of the mouth is brought about by spasm induced through the painful eruption of a wisdom-tooth, occurring as it does in early life, the teeth in the front of the mouth are almost always firm, and would readily bear the wedging force. Upon introducing the point of Mr. Maunder's 'gag' between the incisors, or canines, or premolars, and slowly turning the instrument, it evenly and in regular progress separates the jaws, and, as I have thought, with quicker results than any other method. Very favourable results have been obtained with Coleman's gag, associated with anaesthetics.

In extracting an impacted wisdom-tooth one accident will occasionally arise; namely, the crushing of the inferior maxillary nerve beneath the tooth-fang. It is immediately attended by loss of feeling in the teeth and lower lip of that side. This has occurred twice to myself. In each case sensation slowly returned and was quite re-established in a few weeks.

III. *Tumours of the gum.*—(a) Epulis; (b) Congenital hypertrophy of the gum and alveolar borders of the maxillæ; (c) Polypus of the gum; (d) Vascular tumours; (e) Warty tumours of the gum.

Epulis.—The term "epulis" has been vaguely applied to various tumours that are found in and beneath the gums. The etymological meaning of the word (*ἐπί, upon, ὡς, the gums*), entirely referring to position, and not to structure, is likely to have caused and to continue this confusion. Where, however, distinction has been drawn, it has been applied to those hard and densely fibrous tumours that arise from the surface of the alveolar processes, involving the periosteum, and by their expanded growth stretching the otherwise healthy gum over them. These are essentially different in origin, history, and anatomical structure from the loose flaps, and often pedunculated masses of gum, mere hypertrophied integument, that are not unfrequently seen in the neighbourhood of decayed teeth, and to which

the designations "polypus" and "fungus" of the gum have been appropriately given.¹

An epulis tumour consists of a hard dense mass growing slowly and evenly from the edge of the alveolar process usually between two standing teeth, and more commonly on the labial or buccal aspect than the lingual. The point at which this growth generally makes its first appearance is beneath and involving the little tongue of gum which exists between the necks of two contiguous teeth. As it progresses in size, it displaces the neighbouring teeth, one usually more than the other; it has for the most part a broad base, and increases in basal area more than in projecting growth. The situation in which an epulis commences is liable to a good deal of variety; though usually at the free edge of the alveolar process, it may form at a distance from it; but I believe it is always associated with porous vascular bone, nearly connected with the periodontal membrane, and does not spring from the compact tissue limiting the outline of the bone. The growth sometimes commences in the tooth-socket. As I have remarked, the endosteal membrane shares in the genesis of an epulis tumour, and the fibrous growth appears to burrow, so to speak, into the substance of the bone, producing a general expansion of the whole structure. The surface of the tumour is like that of the surrounding gum; it is, however, sometimes mottled, and not infrequently slightly but broadly and flatly lobulated. It is as insensitive as the surrounding gum, and is not liable to bleed; when manipulated, it is tense and elastic. The tumour varies in size indefinitely from the size of a pea to that of a walnut, or larger. It is generally stated that epulis tumours are more common in the upper than in the lower jaw; this coincides with my own experience. I happen to have met with them in the proportion exactly of two of the former to one of the latter. According, however, to Mr. Heath's table, he has met with twelve cases of epulis in the lower jaw to nine in the upper. The epulis tumour appears to have a certain relation to the teeth in whose neighbourhood it forms. It almost always makes its appearance where there are teeth: it usually invades one in a very marked degree more than any other near which it may be situated, by dislocating it and pushing it out of place: it has nothing to do apparently with caries of the tooth: the removal of the particular tooth, with excision of the tumour, is generally accompanied by immediate and complete cure of the disease.

Occasionally these tumours appear where teeth have been removed and the gum seems to be edentulous; it will, however, generally be found in these instances that a fang of one of the teeth has been left behind, and is associated with the irritation that has caused the morbid growth. One of the most severe examples of this malady which I have seen consisted of a bilobular mass, the size of a large walnut, extending, on the left side of the lower jaw, from the dens sapientie to the canine tooth, the four intermediate teeth having been removed. The excision of the tumour had been repeatedly performed, but it always returned. Its removal on this occasion disclosed the remains of one fang of the first molar tooth in its very axis; this was extracted, and the disease did not again make its appearance. I believe this will generally be found the case where the tumour forms upon an apparently edentulous region of the jaw. Epulis has its origin in the osteal membrane of the alveolus. The bone of the alveolar processes is very vascular, and almost cancellated in its loose open structure. The endosteal membrane which lines this cancellated bone, the periosteum which covers it, and which lines the tooth-sockets and the fibrous tissue of the gum, are all continuous, and alike share in the development of an epulis tumour. The bulk of the tumour consists of a dense web of fibrous tissue; and from its basal attachment, and passing into its substance, are usually small growths of bone. The fibrous tissue interlaces pretty regularly—some fibres being parallel to the surface, and others radiating from the base, intersecting the former at right angles. The bone-growths may be thin needle-like spicula or little flakes: at the point whence these bony processes arise, the tumour receives its main vascular supply, and the subjacent bone is very porous. Mr. Cesar Hawkins mentions an instance

¹ *Specimens of Epulis*, by S. J. A. Salter, *Trans. Path. Soc.* vol. v. 1854.

of an epulis attached only by a pedicle to the gum, in which there was a nucleus of bone. This could not at any time have had bony union with the jaw; but the circumstance indicates, in a physiological sense, the osteal character of these fibroid developments. Epulis tumours are perfectly innocent, nor do they, I believe, ever pass into a malignant character. Sometimes, though rarely, they ulcerate on the surface; but this is only under the influence of external agencies, such as produce ulceration of any portion of the gum: they may then become painful.

The histology of epulis tumours is consistent with their history—locally recurrent as long as the circumstances under which they occurred are maintained, destroyed by the removal of their local nidus, and never impregnating the system. Epulis tumours are always, I believe, a form of 'fibro-plastic;' a combination of fibrous tissue and myeloid cells, the proportion of the two constituents varying indefinitely. In general, the main bulk of the tumour consists of fibrous tissue; but sometimes the myeloid-cell element preponderates, and may form the major portion of the growth.¹ According to Mr. Heath, the myeloid form preponderates in the lower jaw and the fibrous in the upper.

The treatment of epulis is very simple; it requires early and complete extirpation with the knife, and according to the extent and inveteracy of the case it may also need the removal of contiguous teeth and subjacent bone. These latter circumstances refer to an important circumstance in the *pathological history* of the disease: it is this, that as long as the alveolar process remains upon which the tumour grew, and which must necessarily be as long as the teeth which are implanted in it are not removed, so long will the tumour be inveterate, so often will it return, however accurately and carefully it may have been removed. Such, at least, is the very general rule. But when the alveolar process is gone, it shows no tendency to return. And it is a remarkable circumstance, that the spontaneous absorption of the alveoli that follows the extraction of the teeth is of itself, in many instances, where the disease is confined only to these processes, enough to prevent its recurrence. That is to say, if the tumour be removed to a level with the gum, and the contiguous teeth be extracted, the alveolar process vanishes, by absorption, and the disease no more returns; though the same operation, without the removal of the teeth, may have been performed unsuccessfully any number of times previously. In a first operation when the disease is of limited extent, it will be well to try the result of its simple removal by the scalpel without the extraction of teeth or the cutting away of more bone than can be accomplished with the knife. The bone about the base and axis of the tumour being vascular and spongy, the knife readily cuts away small portions. Any subsequent sprouting of granulations in an undue or threatening degree should be checked and repressed by some caustic, and for this purpose nitric acid has been especially recommended. If the disease recurs, as it too often does, the same operation should be repeated, and accompanied by the extraction of a tooth or teeth whose socket or sockets have been implicated. Unless the disease have a deep hold on the bony substance of the jaw, it will seldom be necessary to cut away any large amount of bone; sometimes, however, this is the case; or the growth may have started deep in the socket of a tooth. In such an instance, it may be necessary to extirpate a considerable amount of bone. A V-shaped portion or a cubical mass may be readily cut out by means of a Hey's saw and bone-nippers, according to the form and extent of the particular tumour. It will never, I believe, be necessary to go far below the limit of the alveolar process; for it is with the alveolar bone that the disease is essentially connected. In the lower jaw I would urge the necessity of never cutting through the alveolar bone, as the breaking of the maxillary arch most seriously interferes with the position of the remaining portions of the bone, and thus disturbs the normal opposition of the teeth in the two jaws relatively.

Congenital hypertrophy of the gum and alveolar borders of the maxillæ.—In 1859 I had an opportunity of seeing a very remarkable example of disease, which is, perhaps, best defined by the above title, under the care of Mr. Pollock, at St. George's

¹ *Specimens of Epulis*, by S. J. A. Salter, *loc. cit.*; 'Myeloid Epulis of Lower Jaw,' by J. Hutchinson, *Trans. Path. Soc.* vol. viii.

Hospital. At that time there was, I believe, no recorded example of this curious tumour-like growth; nor had any instance of it been published as far as I am aware, until a case was described and figured by Gross in the second edition of his '*System of Surgery*.'¹ This case was not only the same in essence, but was singularly like Mr. Pollock's in all particulars.

Similar cases have since been recorded. One occurred in University College Hospital under the care of Mr. Erichsen, and is described by Mr. Heath.² Another is published by Mr. Waterman,³ an American surgeon. Three examples have been recorded by Dr. Murray,⁴ and two more recently by Mr. Heath.⁵

Mr. Pollock's patient at the time of her admission into the hospital was eight years old. At birth nothing was noticed unusual in her mouth, but a fortnight after a tooth was cut, and by the fifth week six had appeared. It was then remarked that the gums were full and thick, and puffy. They continued to increase in bulk, and at two years of age they were cauterised, and all the temporary teeth which had appeared were extracted. At birth the child had an unusual quantity of hair on the head, and also much on the arms and legs: when taken into the hospital this peculiarity was very striking; the hair of the head was coarse and rank, and grew low on the forehead, and in front of the ears on to the cheeks. The arms and legs were covered with hair. The patient was epileptic.

Before any operation was performed, the girl presented a most extraordinary appearance. A large mass, pink and smooth, protruded from the mouth, which the lips did not and could not cover. It was slightly corrugated or indistinctly lobed; the structure was very dense, inelastic, and insensitive, and appeared skin-like on the surface. The greater bulk proceeded from the upper jaw, and was most developed in the front of the mouth; but the same condition appeared along the whole edge of both jaws, that of the lower jaw being less, and covered and overlapped by the upper.

In structure this hypertrophied mass consisted both of an expanded and prolonged development of the alveolar borders of the maxillæ, and an immense thickening of the fibrous tissue of the gum, with a proportionately exuberant growth of the papillary surface. The removal of portions of the mass by surgical operation gave opportunities of examining its precise nature. In the front of the upper jaw, where the development was greatest, the fibrous mass extended in some places more than three quarters of an inch beyond the alveolar edge, which it thus covered in with a dense cushion. Those of the temporary teeth which had not been extracted were deeply embedded in the mass, the crowns of the second lower temporary molars being the only ones which were now visible. The crowns of all four of the six-years' old teeth (first permanent molars) had appeared on account of the slightness of the hypertrophy towards the back of the mouth. A section of parts of the removed mass displayed the remaining temporary teeth completely clothed with the thick fibrous growth, the fangs embedded in sockets, but the crowns free of bone and each closely surrounded by a serous-like chamber without any communication with the surface. One of the superior central incisors was more deeply covered than any other teeth, and was nearly an inch from the surface. The fangs of the permanent teeth were developed in accordance with the age of the patient; but I observed that the crowns were still encased in the bony loculi, though from the age of the patient the distal wall of the bony capsules should, in many of them (incisors and first premolars), have been absorbed. In the socket of the first temporary incisors a small absorbed orifice existed, leading into the locus of the permanent teeth, such as is usually found about five years old.

But the most remarkable point of structure in this growth was the papillary surface. The epithelium had changed into a very thick and hard epidermis, beneath which, and evenly covered in by it, were enormously long papillæ. The papillæ of gum vary from about $\frac{1}{7}$ th to $\frac{1}{4}$ th of an inch in length normally; but in a section, vertical to the surface, they here appear from $\frac{1}{8}$ th to $\frac{1}{4}$ th of an inch; and when by maceration the outer epiderm has been removed, the papillæ stand up like the pile of plush or velvet, and may be brushed from side to side by the finger. Kölliker⁶ has noticed that in the mouths of edentulous old people, whose bare gums are exposed to the rough attrition of food, the papillæ become much enlarged and elongated, attaining sometimes the $\frac{1}{16}$ th of an inch in length: and here, under exposure to still more physical violence, the same change has taken place to a vastly greater degree. But I apprehend that this monstrous development of the papillæ has also another meaning, and that it is an essential element of the disease; it is quite in keeping with the

rough and thick skin of the patient, the abundant development of coarse hair over the surface, and also the enormous teeth. The permanent teeth which were removed by the operations are excessively large, especially the superior central incisors; these are larger than any I have before seen removed from a female mouth. All these circumstances imply a tendency to a general tegumentary and papillary hypertrophy.

Treatment.—The proper treatment of this disease is obviously that which was followed in each of the recorded cases. Portions of the projecting mass were cut away with scalpels and bone-nippers till the alveolar borders were curtailed to within moderate limits. The operation was not completed at once, but was performed in detail, as the patients could bear it. In Mr. Pollock's and Dr. Gross's cases there was a slight tendency to a fresh growth where the hypertrophied masses were removed.

Polypus of the gum.—The gum is liable to a simple hypertrophy, the increase of growth—a sort of mucous tubercle—being confined to the gum structure alone, and not involving the osteal membrane, nor complicated with a growth of bone. The little tongues of gum between the necks of the teeth are liable to this affection, especially towards the front of the mouth; and they sometimes grow to such an extent, being confluent with those on either side, as to cover a considerable portion of the crowns of the teeth. This condition is usually associated with uncleanly habits; and may be generally cured and prevented hereafter by simple and easy means. The teeth should be thoroughly cleansed from tartar; the gums may be scarified: for the future the teeth should be abundantly brushed with a stiff brush, and the mouth washed with an astringent lotion, of which solution of permanganate of potass may form an ingredient. I have seen a modification of this condition, which was evidently syphilitic; the growths of the gum were *condylomatous*, and were more or less covered with very painful superficial ulcers. The symptoms readily yielded to the internal administration of iodide of potassium and the application with a camel's-hair brush of a solution of nitrate of silver, 10 grs. to ℥j. aquæ. Hypertrophy of the gum of a truly polypus-like form not infrequently occurs in the immediate neighbourhood of teeth which are carious at their sides, and when the caries reaches the neck of the tooth: the irritation of the contiguous dentinal disease seems to stimulate this unwonted growth, and the mucous membrane bulges into the cavity and fills it up. The cavities of two teeth carious on their contiguous surfaces are very apt to be associated with this condition, the little polypus of gum between them rising to their masticating surfaces. Such tumours are more or less pedunculated; they have a red fleshy look, and are very liable to bleed when roughly touched. The structure of these growths is in consonance with their aspect and the ease with which they bleed; they consist principally of hypertrophy of the true mucous-membrane element of the gum, especially the papillary structure: the epithelial covering is rather diminished in proportional amount, while the papillæ themselves become enormously elongated and increased in diameter, and some of the conical papillæ develop into the compound fungiform variety. These changes are accompanied by great dilatation of the capillaries which loop into the papillæ.

Polypous growths of the gum are so often dependent on the state of the contiguous teeth, that their treatment involves that of the teeth also. If the polypus, growing into a carious tooth, is extirpated, it will most probably return till the tooth itself is removed, or the condition of the tooth which had irritated the gum has been remedied. The caries should be cut away; ragged or sharp edges of tooth-substance should be smoothed and blunted, and the remaining cavity should be filled. The gum may still show some tendency to renewed sprouting, and this may be kept down for a time by the repeated application of a strong solution of nitrate of silver sulphate of copper, or alum, when it will probably assume a healthy aspect. If the removal of the polypus is accompanied by the extraction of the offending tooth, I believe it never returns.

Vascular tumours.—The tissues about the necks of the teeth are obnoxious to the growth of vascular tumours, which vary from passive *nervus-like* swellings to those other forms of more arterial character—*aneurisms by anastomosis*. I have met with

both these forms of the disease. The most common position in which it develops itself is in front of the upper jaw, between the incisors, or canines and lateral incisors. A rather severe instance which occurred recently under my care manifested itself in the region that should have been occupied by the left lateral incisor of the upper jaw; but as the laterals were wanting in this person, the tumour formed between the canine and central incisor. It had been about six months in reaching its then size, the dimensions of a large marble flattened on the surface. It was of a purplish colour, streaked with many vessels on the surface; it was easily compressed, but was elastic, and when pressed it became pale, exsanguine, and much reduced in size; upon removing the pressure it resumed its previous aspect in a pulse or two. The surface of the growth was tolerably smooth; the base somewhat constricted, being about one-third less than the head of the tumour. The whole of the gums were very red, turgid, and swollen, and the little tongues of gum between the necks of the teeth generally were enlarged and spongy. The patient had suffered no pain, but was conscious of a constant throbbing and pulsation. The most important symptom, however, was the hæmorrhage, which had latterly become a serious source of trouble and distress; it usually occurred at night, it would ooze from the mouth and stain the pillow and sheets, and sometimes trickle into the glottis and cause momentary suffocation.

The treatment which I first adopted in this case was determined by the very *arterial* character of the tumour. I attempted to destroy it by ligature—a needle armed with a double thread was passed through its base, and each portion of the thread was tied so as to strangulate half of its attachment. The ligatures were tied tight, but did not cut through the substance of the growth. Their effect was for the time to produce complete strangulation: the tumour was tense; and the blood could not be squeezed out of it by pressure. This plan did not ultimately succeed, for the size was not permanently diminished and the circulation was re-established. I next removed the tumour by a very tight ligature, cutting it clean off; after this it returned as before, and I finally extirpated it with a scalpel, cutting freely inwards so as to remove a portion of the spongy vascular bone which seemed to form its basal axis. The bone at the base of these growths appears always to be very vascular and open in its texture. Considerable hæmorrhage followed the operation, which ceased under cold and pressure. For a few weeks the cicatrix furnished freely sprouting granulations; these were abundantly cauterised twice a week, and ultimately yielded a healthy scar. In structure this little mass when removed displayed a complicated vascular network, which, under the action of acetic acid, with the microscope, exhibited little else than an elaborate aggregation of the nuclei of blood vessel muscle-cells. The surface was clothed with epithelium and papillæ, like the gum. I believe that no danger can arise in these cases from the use of the knife in at once extirpating the tumour; the bleeding may be profuse for a minute or two, but it soon ceases.

I have seen a vascular tumour connected apparently with the periosteum of a loose molar tooth, in which the hæmorrhage was very severe, occurring also at night to an extent that was really alarming: the tumour was a tense pedunculated mass, attached to the side of an upper molar tooth, half of the fang of which was naked. The extraction of the tooth brought away the tumour with it, which immediately shrivelled up to half its previous volume, and became soft and flabby.¹

These tumours, as far as I have observed, occur in adult and middle life; they are perfectly innocent, and show no tendency to return when carefully eradicated.

Warty, or papillary tumours of the gum.—The papillæ of the gum occasionally become hypertrophied into warty growths. A singular instance occurred in the practice of Sir William Fergusson, in which the papillæ were more than half an inch in length: they were soft and shreddy, and consisted mainly of loosely adherent epithelium. The tumour was removed, and recurred several times. Another

¹ 'Vascular Tumours connected with the Dental Periosteum,' by S. J. A. Salter; *Trans. Path. Soc.* vol. v. 1854.

example was operated on by Mr. Cock, at Guy's Hospital, in which a warty tumour, the size of a split chestnut, formed in the hard palate of a man.¹ This was covered with papillæ the eighth of an inch long. It consisted principally of fibrous tissue and dense coherent epithelium. I have seen a profusion of small warts on the gums associated with warts on the lips and about the face. In all cases the growths should be removed with the knife; and any recurrence should be repressed by caustic or astringent applications.

IV. *Tumours of the pulp. Polypus of the pulp.*—In carious teeth the tooth-pulp is occasionally developed into a polypus-like growth, that fills more or less the diseased cavity. This formation is a dense, gristly, pink-coloured mass, consisting of a modification of the original dentine-forming organ: it is always attached by a constricted base to the pulp in the canal of one or more of the fangs; the mass itself is usually more or less rounded, frequently corresponding in form exactly to the carious cavity which contains it; sometimes, by a more exuberant growth, it is forced into a polyhedral shape by the contiguous structures, whose pressure curtails its further enlargement—the masticating surface of the opposing tooth in the other jaw, the distal and proximal neighbours of the tooth from which it has sprung, the tongue and the cheek; such cases as these usually occurring where the walls of the original tooth have completely broken away, leaving a distinct interval bounded by the parts I have named. In such examples it may be difficult to an inexperienced observer to make out the nature of the tumour; it may be mistaken for an *epulis*, or a gum polypus; search for the remains of the decayed tooth will settle this doubt. This polypus is very callous and insensitive to pain: it is not liable to ulcerate or bleed; but it discharges pus from its surface, especially when in contact with the walls of the carious tooth in whose cavity it forms. In structure these polypi approach, in the majority of instances, very closely to the ordinary granulations of a healing sore, consisting superficially of a mass of exudation corpuscles, through which are distributed multitudes of capillary loops, and more deeply of a fibrous tissue into which these cells have developed. In these instances the most superficial cells appear to be shed, assuming the form and aspect of pus. Rarely these granulations seem to heal, to cicatrise; and I have found a few instances in which the surface of the polypus has been clothed with a dense cuticular epithelium overlying a basement membrane folded into true papillæ. Polypus of the tooth-pulp 'most often occurs in young people, and in those in whom the teeth are imperfectly calcified, presenting that peculiar globular calcification in which the substance of the dentine becomes rapidly sodden with saliva, and carious without limit from the enamel to the pulp.' 'The physiological phenomena displayed by polypus of the pulp are very remarkable as regards both the pulp itself and the tooth—their oppositeness to the whole train of circumstances which accompany the ordinary inflammation of the pulps dependent on caries, odontalgia, lymph-deposit on fangs, alveolar abscess, &c. . . . The pulp never undergoes intrinsic calcification, nor have we any evidence that dentine of repair is ever formed.'² Occasionally, though very rarely, teeth with polypus of the pulp produce alveolar abscess.

The treatment of this condition is very simple. If the polypus is cut away, it will certainly return; caustics and the like applications appear to have no influence in repressing it. If the tooth be extracted, it is finally eradicated; and this plan should in my opinion always be adopted.³

Sensitive growth of pulp after fracture.—This condition only occurs, as I believe, when a tooth with a healthy pulp is suddenly fractured by mechanical violence. When a pulp is thus exposed, it exhibits intense sensitiveness to touch, to cold or

¹ 'Papillary Tumours of the Gum,' by S. J. A. Salter, in *Guy's Hospital Reports*, 3rd series, vol. xii. p. 358.

² 'Polypus of Tooth-pulp,' by S. J. A. Salter, *Guy's Hospital Reports*, 3rd series, vol. iv. 1868.

³ I learn from Mr. Coleman that he has once succeeded in saving the tooth by excising the growth, touching the pedicle with strong nitric acid, capping, and filling the cavity with stopping.

heat, or indeed to any external influence; and it frequently sprouts into a small excrescence. This excrescence is usually of a semi-transparent aspect; it is often complicated on the surface, and villus-like: when removed, like the other form of pulp growth, it certainly returns, and of the same character as before. In microscopic structure this sprouting of the pulp differs little from the insensitive polypus; but its vitality implies a more abundant nervous supply—vascular granulations appear to the observer to constitute its histological elements. This condition remains as a permanent torture to the patient, till the tooth is extracted, when it is of course completely removed. I have known this state of tooth-pulp form a very distressing complication in a case of fracture of the lower jaw, in which a bicuspid tooth was broken and the pulp exposed: here the apparatus for fixing the displaced bone, and the introduction into the mouth of food, were attended with agonising pain, which continued till its source, a fractured tooth with a quick pulp, was discovered and extracted. Afterwards the treatment of this fracture was successfully and painlessly prosecuted. The possibility, indeed occasionally probability, of such complication, in treating fractures of the maxilla, should be borne in mind by surgeons; and it should be especially remembered, that when extreme sensitiveness and pain manifest themselves in such cases, a fractured tooth should be sought for.

V. *Tooth tumours. odontomas.*—The hard tissues of teeth are sometimes developed into tumours, which may be divided as follows:—

- (a) Enamel nodules, or submerged cusps on tooth fangs.
- (b) Exostosis.
- (c) Hypertrophied, dilated fangs.
- (d) Dentine excrescence.
- (e) Warty teeth.

Enamel nodules are sometimes seen on the fangs of teeth, forming little pearl-like tumours: they are essentially *submerged cusps*, each consisting of a little cone of dentine, covered by a thick tubercle of enamel, which is clothed by a true enamel pulp.¹ These tumours are not known to occasion any symptoms; and are rather of physiological than surgical interest: indeed they are alluded to here, simply to complete the list of tooth-tumours.

The accompanying illustration (fig. 109) is taken from a characteristic specimen.

Exostosis on the fangs of teeth is sometimes a serious malady. An increased development of crista petrosa may occur upon the fang of a tooth as the

secondary result of other disease in the tooth—usually caries; or it may arise spontaneously—the tooth being entirely free from other abnormal change.

In the former case the thickening of the fang is usually general, around its circumference and principally on its lower third, as repeated in fig. 110. The symptoms of this condition are scarcely to be distinguished or separated from those of the tooth-disease with which it is associated.

Where the disease arises spontaneously it is apt to produce the most distressing neuralgic affections. The teeth appear sound, but they become sensitive to change of temperature and even to the touch: they elongate from the sockets and spread; with this there is more or less neuralgia of the trigeminus, or one of its terminal branches. Then one particular tooth becomes more distinctly affected than the others: all the pain seems to emanate from it: and each flash of neuralgic agony seems to start from it alone. At length the tooth is extracted and relief follows. Then usually another tooth becomes affected and requires removal: and this may, in very severe cases, go on till all the teeth in one jaw, or even in both, have been

FIG. 109.

FIG. 110.

¹ For the structure of these growths, see 'On Two Forms of Tooth-tumours,' by S. J. A. Salter, in *Guy's Hospital Reports*, 3rd series, vol. xiv. 1869.

extracted before complete and permanent relief is obtained.¹ In these cases the exostosis usually consists of small nodules with rounded surfaces situated near the apex of the fang. Such forms of exostosis may, however, exist without producing any apparent symptoms whatever. Fig. 111 represents a magnified section of the fang of a tooth in which this nodular form of exostosis existed.

Exostosis on the fangs of teeth consists solely of an hypertrophy of the crusta petrosa, or tooth bone, the outer layer of the fang. It is usually solid and compact in structure: though very rarely it is cancellated and vascular.²

Hypertrophied, dilated fangs.—This title best defines the nature of a very rare form of tooth-tumour, of which I believe there are only four recorded examples. One of these occurred in the practice of M. Maisonneuve and is described by M. Forget;³ another occurred to Mr. Hare of Limerick, and is described by Mr. Tones;⁴ another is described by Heider and Wedl;⁵ and a fourth is a specimen in the Museum of the College of Surgeons of England (Preparation 1022) which has been histologically examined and described by myself.⁶ The latter is supposed to have been in the collection of John Hunter. The first two of these examples were mistaken for exostoses.

These tumours consist of dilatations of the fangs of the teeth; the dentine-pulp being hypertrophied into a globular mass of considerable size; and, when calcified, producing a bone-like mass, generally larger than the tooth itself. In structure

FIG. 111.

FIG. 112.

FIG. 113.

these tumours consist of an outer layer of tooth-bone; then a thin shell of true dentine, enclosing the gigantic pulp, which may or may not be calcified. In the former case, this bulky nucleus of the tumour consists of a mass of osteo-dentine.

In the only two cases in which the symptoms were recorded, there was pain with expansion of the jaw at the alveolar portion. In Mr. Hare's case there was a fistulous communication from the tumour through the jaw opening on the cheek. This discharged pus.

In each case the extraction of the tooth brought away the tumour also: the swelling subsided, and the patient recovered completely. Fig. 112 represents the specimen in the Museum of the College of Surgeons.

Dentine excrescence. Nodules of secondary dentine growing from the wall of the pulp-chamber into its cavity in teeth otherwise apparently healthy, are sometimes seen, though they have not generally been associated (perhaps from imperfect observation) with any definite symptoms. The accompanying illustration (fig. 113), however, represents an example⁷ where the little tumour evidently produced

⁷ 'Dentine Excrescence within the pulp-cavity of the Incisor Tooth,' by S. J. A. Salter, *Path. Trans.* vol. vi. p. 164, fig. 1. 1855.

neuralgia, of a character very similar to that occasioned by exostoses on the fangs of teeth. The tooth was a superior central incisor, which was constantly painful: the slightest touch or change in temperature augmented the pain considerably, when it often flashed over the face and nerves of that side of the head with great severity. The extraction of the tooth, which was for the moment attended with a violent paroxysm of neuralgia, completely removed all subsequent pain. The dentine-excrecence was the only abnormal condition which the tooth presented. Its pressure upon the nerves of the pulp would readily explain the symptoms of the case.

This anatomical condition is not altogether uncommon, but it seldom causes painful symptoms.

Warty teeth.—These are among the rarest and most important of the tooth-tumours. They consist of teeth in which the tissues are hypertrophied and folded into an irregular and complicated mass. The warty condition may affect part of the crown of a tooth; or all the parts of the tooth may be involved; or the irregular mass may consist of teeth blended together.

M. Broca, in a general résumé¹ of this subject, which he read before the Academy of Sciences of Paris (December 30, 1867), divides warty teeth into 'circumscribed dentinal odontomes,' and 'diffuse dentinal odontomes;' the former being those examples in which the warty mass occupies a portion of the tooth only; the latter, in which the whole tooth is implicated, and its anatomical form is no longer recognisable.

Warty teeth are rare, and I am only acquainted with twelve recorded examples—six of the circumscribed variety and six of the diffuse. Of the former, four were described by myself,² one by Mr. Tomes,³ and one by Forget,⁴ of the latter, two were recorded by Oudet⁵ (in the same individual), one by Wedl,⁶ one by Mr. Tomes,⁷ one by Forget,⁸ and another by Mr. Harrison.⁹

FIG. 114.

In the cases recorded by myself, one was a superior lateral incisor with a warty mass, the size of half a horse-bean, projecting from the front of the neck of the tooth. A section of this tooth for the microscope is in my histological collection. A second case, which occurred in my own practice, was that of a right lower dens sapientiae. The mass, about the size of a small bean, sprouted from the posterior aspect of the neck of the tooth. My two remaining examples are specimens in the Museum of Guy's Hospital: one a lateral incisor, and the other a wise-tooth, both of the upper jaw: from the side of each tooth a warty mass projected. The accompanying illustration (fig. 114) represents the lateral incisor referred to.

Mr. Tomes's specimen was a superior central incisor: the wart occupied the whole of the front of the crown of the tooth. In Forget's example, the first and second lower molars were blended into one: the crowns constituting a large confused wart-like body, while the fangs were normal. This is shown in fig. 115.

⁹ *British Journal of Dental Science*, vol. v. p. 557. London, 1862.

The diffuse forms of warty teeth, which have produced large cumbrous tumours, have all been developed in the lower jaw. They deserve more serious consideration.

In Oudet's case a man, twenty-five years of age, exhibited in his lower jaw two hard bony tumours, occupying the premolar region one on each side. They were encrusted with salivary calculus, upon the removal of which an irregular coating of enamel was displayed, folded into shapes like cusps and tooth-edges. These masses were evidently formed from the fused and hypertrophied germs of the two premolar teeth on both sides of the jaw. The right was removed rather easily by tooth-instruments, but the patient declined to have the other interfered with.

In Wedl's case the whole of the second lower molar tooth of the right side was developed as a large complicated mass in which the several tissues of the teeth were confounded together. It was overlying and keeping down the wisdom-tooth. With a pair of forceps it was removed without much difficulty.

The specimen described by Mr. Tomes is exactly the same as the foregoing. It consisted of a confused mass of dental tissues as large as a chestnut, representing the second lower molar tooth, beneath which was buried the wisdom-tooth. It occurred many years ago in the office of Sir William Feiggusson, who excised the angle of the jaw for its removal.

But M. Forget's is the most serious recorded example of this malformation. Here an enormous tumour, as large as a turkey's egg, occupied the whole of the molar region of the

FIG. 116.

FIG. 115.

left side of the lower jaw. It represented two molar teeth with their tissues blended together in utter confusion and into a shapeless mass. Beneath it was a third molar tolerably well formed. The jaw began to expand in early childhood, and continued to do so till the patient attained the age of twenty, when M. Forget removed the angle of the jaw, including the tumour. The mass was covered by gum, excepting for a space on its surface the size of a sixpence. There was some pain at times: the submaxillary glands were enlarged, and several fistulous pus-discharging canals led to the base of the tumour. The accompanying illustration (fig. 116) is from Forget's memoir, and displays a section of the tumour *in situ*.

Mr. Harrison's specimen represented the two bicusps and canine of the left side on the lower jaw. The tissues were confounded together, and without any resemblance to tooth-form. It loosened and came away by itself.

As regards the treatment of these cases, much depends on the degree of the malformation. If it is only partial and a matter of appearance, the tooth may be removed and replaced by a better-shaped artificial representative, according to the wishes of the patient. But should the growth be of a large size and interfere with the action of the mouth, it should certainly be extirpated; and this, in nearly all instances, might be accomplished by extraction with forceps; or, at all events, without serious damage to the jaw.

VI. '*Abscess of the antrum*.—The term *abscess* of the antrum conveys a very wrong impression of the real nature of this disease; it is not the suppuration of inflamed parenchyma, but the occlusion in a cavity of the purulent secretion from

the surface of a mucous membrane which lines that cavity. I need not dwell on the anatomical characters of the antrum maxillare further than to notice its peculiar relations to those organs, the teeth, whose affections are by far the commonest cause in the production of the malady we are considering. These relations vary extremely, both as regards the extension of the antrum over the fangs of many or few teeth, and the degree in which those fangs approach or pierce the floor of the sinus. It may extend so as to be in immediate relation to all the teeth of the true maxilla from the canine to the dens sapientie, or it may be contracted to such narrow limits as only to correspond with two or three of the central ones. This variation in the size of the antrum is not mentioned in text-books of anatomy, but it is pointed out by Otto.¹ Occasionally a root or roots of the first molar tooth (rarely any other) extend into the cavity, free of any bony covering, and merely overlaid by the mucous membrane lining the sinus; more often, however, the palatine and external roots diverge so as to leave an interval between which the more depending sulcus of the antrum is excavated. Another circumstance in the anatomy of the antrum bearing on the purulent accumulation which constitutes abscess of this sinus, is the very variable size of the orifice which opens into the middle meatus of the nose. In some instances the aperture is barely sufficient to admit the blunt point of a probe; in others it would allow the passage of the end of the little finger. It is always much smaller in the living state when the mucous membrane lines and fills up the opening; indeed, it is the pouting of the tumid mucous membrane which closes the orifice in inflammation. The lining membrane of the antrum is liable, like all other mucous membranes, especially the Schneiderian membrane, of which it is a continuation, to inflammation and altered secretion, mucus being impregnated with or replaced by pus, and accumulating in quantity. This may occur in different degrees, both as to amount and rapidity of development; but the circumstance which here gives importance to this altered and more abundant secretion depends entirely upon the fact that it may become occluded within the sinus by means of the swelling and turgescence of the mucous membrane around its orifice. This, from such anatomical arrangement, converts a mere catarrhal inflammation, spending itself by superficial pus-shedding, into a shut expanding sac, in many respects equivalent to a deep-seated abscess, though by no means identical with that condition either in pathological history or absolute anatomy.

The *causes* of abscess of the antrum may be enumerated in very narrow limits. I believe that in adults, in the majority of cases beyond all computation, it is produced by dental caries, or at least by alveolar abscess, in some stage, associated with tooth-disease. It is stated that the affection may be brought on by a blow on the cheek; and an instance has been recorded in which the malady has occurred in a new-born child, and was supposed to result from the pressure on the cheek during a hard labour.

The *symptoms* of antral abscess vary much in degree; but they usually commence by dull aching pain in the cheek, with heat, redness, and fullness of the soft parts externally. In the early stage there may, or may not, be a purulent discharge from the corresponding nostril; this, however, can only occur to any marked extent before the aperture between the middle meatus and the sinus is closed. As the case advances and the matter becomes pent up, the pain assumes a throbbing character and is severe, and constitutional symptoms manifest themselves analogous to those of acute abscess; the patient has rigors and fever. With this the local symptoms change, and an expansion of the whole jaw shows itself; the malar bone becomes elevated, the fossa beneath it full and prominent; the molar teeth on the affected side appear to elongate, and, in closure of the mouth, meet their opponents too soon; the concavity of the hard palate becomes flat or even convex; the nostril of that side is more or less closed, and, in severe and protracted cases, the floor of the orbit becomes so pushed up as to protrude the eye. Hunter, in describing the symptoms of antral abscess, speaks of the eye being sometimes 'affected;' but in what manner

¹ *Lehrbuch der pathologischen Anatomie des Menschen und der Thiere*, von Dr. A. W. Otto, p. 180. Berlin, 1830.

he does not specify. Beyond instances in which protrusion of the globe¹ has occurred few have been recorded. The inflammation accompanying abscess of the antrum is, however, occasionally so severe as to implicate the periosteum, not only to the destruction of some parts of the maxilla, but extending beyond to contiguous fibrous structures, so as to involve the optic and other nerves in their passage from the cranial cavity to the orbit, producing blindness and fixedness of pupil on the affected side. Such cases are very rare; but one has occurred in my own practice at Guy's Hospital;² a second was under the care of Mr. Pollock; and a third is mentioned by Dr. Brück in Casper's 'Wochenschrift.'³ Necrosis of part of the jaw is one of the rarer accompaniments of this malady; but when any portion of the bone is affected, it is usually either the alveolar processes or the nasal plate of the maxilla.

The manual examination of the jaw seldom fails to indicate the fluid nature of the distending material; fluctuation can be felt, and the thinned bony parietes of the abscess convey to the touch a peculiar sensation, like the handling of dry parchment: as Jourdain very characteristically expresses it, 'quand on appuyoit sur l'os, il s'affaïssoit et revenoit ensuite sur lui-même en produisant une espèce de craquement.'⁴ If any doubt does arise as to the nature of the contents of an expanding antrum, I am in the habit of exploring the cavity with a minute trocar and cannula not above half the size of a wheaten straw; by this means sufficient fluid, if present, may be made to escape to ascertain its nature, and it could scarcely do injury to a solid growth if such were the character of the expansion. A grooved needle would answer the same purpose, but hardly so readily. The fluid may be too dense to pass these narrow canals; generally, however, it is not thicker than ordinary pus, and it is sometimes serous.

The ultimate issue of these cases varies very much. Occasionally the abscess bursts into the nose: sometimes through the cheek; occasionally into an alveolar cavity, burrowing along the fang, and discharging its pus at the neck of the tooth. More rarely the floor of the orbit gives way, and the pus finds its exit somewhere along the lower lid. Occasionally the orifice which communicates between the antrum and the nose yields temporarily, and there is an accommodating escape of pus: as the patient lies on the other cheek, pus will stream from the nostril of the affected side and then stop, and again make its escape by the same exit.

The treatment of this malady is so admirably sketched out by Hunter that I cannot do better than quote his own words:

'The first part of the cure, as well as that of all other abscesses, is to make an opening, but not in the part where it threatens to point; for that would generally be through the skin of the cheek.

'If the disease is known early, before it has caused the destruction of the fore part of the bone, there are two ways of opening the abscess: one by perforating the partition between the antrum and the nose, which may be done; and the other by drawing the first or second grinder of that side, and perforating the partition between the roots of the alveolar process and the antrum, so that the matter may be discharged for the future that way.

'But if the fore part of the bone has been destroyed, an opening may be made on the inside of the lip, where the abscess most probably will be felt; but this will be more apt than the other perforation to heal, and thereby may occasion a new accumulation; which is to be avoided, if possible, by putting in practice all the common methods of preventing openings from healing or closing up; but this practice will rather prove

¹ An extreme case is mentioned by Frank, *De Curandis Hominum Morbis*, &c., auctore Joanne Petro Frank, lib. vi. pars 2, p. 22. Viennæ, 1820.
